head and neck than on the trunk because of limitations in the clearances in the former site. Adjuvant radiotherapy reduces the local recurrence rate when wide local excision is impossible because of anatomical constraints or functional and cosmetic concerns.^{892,953} Mohs surgery can be used in these cases,^{912,987} as well as in recurrent disease.⁹⁸⁸ Chemotherapy is not effective. The tyrosine kinase inhibitor imatinib has been used because it is an inhibitor of PDGFR- α , PDGFR- β , and c-abl (Abelson murine leukemia viral oncogene homolog-1) as well as c-kit and other protein kinases.⁹⁸⁹ These can now all be detected by immunohistochemistry.⁹⁹⁰ It had a profound anti-tumor effect in several reports.^{892,990} It has been recommended that all patients with DFSP receive long-term follow-up, beyond the usually recommended 5 years, due to the risk of late recurrences.⁹⁹¹

Histopathology⁸⁸⁷

Dermatofibrosarcoma protuberans is a dermal tumor that almost invariably extends into the subcutis, where it infiltrates around small groups of fat cells in a characteristic manner (Figs. 34.38 and 34.39).⁹¹⁷ A variant localized to the subcutis has been reported.^{992,993} Deeper extension to underlying muscle is rare.⁹⁹⁴ A superficial grenz zone is often present, but extension to the epidermis, with ulceration, is sometimes seen.⁹⁷⁴ Dermal appendages are surrounded but not invaded.

DFSP is a spindle cell tumor composed of interwoven bundles of rather uniform, small spindle cells with plump nuclei. There are small amounts of intermingled collagen. At points of intersection of the fascicles, there may be an acellular collagenous focus from which the fascicles appear to radiate (Fig. 34.40).⁹⁴³ This is referred to as a storiform or cartwheel pattern. Scattered mitoses are present, but atypical forms are rare. Increased cellularity of the tumor and more than eight mitoses per 10 high-power fields appear to be associated with a predisposition to metastasis.⁹⁴³ Other histological features include an occasional histiocyte and multinucleate giant cell.⁹⁷³ Thin-walled capillaries are randomly distributed. *Fibrosarcomatous* change, seen particularly in recurrences, represents a form of tumor progression.^{887,995} The

Figure 34.38 Dermatofibrosarcoma protuberans. This deep biopsy shows a tumor involving dermis and subcutis. (H&E)

proportion of this element varies markedly from case to case.⁸⁸⁴ The fibrosarcomatous areas may show focal myxoid change,^{915,950} keloid-like hyalinization, giant rosettes,⁹⁹⁶ pigmented melanocytes,⁹⁹⁷ and myoid nodules and bundles.^{998–1001} The leiomyomatous nodules appear to be, at least in part, of vascular origin and reactive in nature.¹⁰⁰² The fibrosarcomatous areas express CD34 in less than 50% of cases.⁹⁹⁷ The expression of fusion transcripts in both conventional and fibrosarcomatous areas supports a common histogenesis of the two components.⁹⁷⁷

Myxoid DFSP is a distinct variant with greater than 50% myxoid stroma.⁹⁷² It is often found for the first time in recurrent lesions.⁹⁸⁴

Figure 34.39 Dermatofibrosarcoma protuberans. Tumor cells insinuate between fat cells in the subcutis and extend into the underlying muscle. (H&E)

Figure 34.40 Dermatofibrosarcoma protuberans. The spindle-shaped cells have a storiform or cartwheel arrangement. (H&E)

There are large myxoid areas that are paucicellular, surrounded by more typical areas with storiform features.¹⁰⁰³ Pigment is sometimes present.⁹⁷² *Atrophic* and *granular cell* variants of DFSP have also been proposed.^{1004–1006} Some cases of DFSP have areas resembling *giant cell fibroblastoma* (discussed previously).⁸⁸⁴ Furthermore, either tumor may, rarely, recur as the other.^{866–868,870,872,883} The related giant cell angiofibroma may also occur within a DFSP.³⁷⁴

The *pigmented* variant has melanin-containing dendritic cells (melanocytes) scattered throughout the tumor.⁹⁶⁴ The amount of melanin pigment is quite variable (Fig. 34.41). Although Bednar reported three cases in which this pigmented variant was present in the core of a nevocellular nevus,⁹⁶⁰ no further examples of this phenomenon have been reported. There is one report of a recurrent DFSP transforming into the pigmented form.¹⁰⁰⁷ Rare cases occur with histological overlap between a pigmented dermatofibroma and a pigmented DFSP.¹⁰⁰⁸ In two recently reported cases, both showed focal positivity for CD34. They did not express factor XIIIa.¹⁰⁰⁸ Both patients were disease-free 2 years later. The various types of DFSP are listed in Table 34.3.

Although usually inconspicuous, the stromal collagen in a DFSP will stain with the trichrome method, but unlike the collagen in a dermatofibroma, it is not polarizable.⁸¹⁸ Sclerotic changes with localized areas of abundant collagen have been reported.^{1009,1010} Meningothelial-

like whorls have been reported in a Bednar tumor.¹⁰¹¹ Immunohistochemical studies have shown that the tumor cells in DFSP contain vimentin,^{975,1012} but they are negative for S100 protein. A few scattered cells may stain for lysozyme and α_1 -antichymotrypsin.⁹⁷⁴ Approximately 80% of cases express CD99.¹⁰¹³ The most diagnostic marker is the human progenitor cell antigen, CD34, which stains 50–100% of the cells in DFSP.^{1014–1019} Conflicting results have been reported in the giant cell fibroblastoma component that is sometimes present.^{870,883} The pigment-laden cells in the Bednar tumor are positive for S100 protein and vimentin, whereas the nonpigmented cells are usually positive only for vimentin.⁹⁶⁷ The expression of CD34 is not present in all cases of pigmented DFSP.^{966,969,1020}

Electron microscopy

The spindle-shaped cells usually have an indented or deeply lobulated nucleus. In some studies, including one concerning the Bednar tumor,⁹⁶⁴ a basal lamina suggesting a perineurial origin was present.^{1021,1022} In other studies, the predominant cell has been interpreted as a modified fibroblast^{1023,1024} or histiocyte.¹⁰²⁵ Of interest are the rare reports in which the metastases of a DFSP have assumed a histiocytic appearance.⁹⁴⁷ The primary lesion in such cases may have been a malignant fibrous histiocytoma incorrectly diagnosed as a DFSP.⁹⁷⁴

Differential diagnosis

Perhaps the most frequent differential diagnostic consideration is **dermatofibroma**, particularly the cellular or deep variants. These lesions may demonstrate increased cellularity and a somewhat storiform arrangement of tumor cells. Dermatofibromas most often show

overlying acanthosis, with flattening of the rete ridges, that is usually lacking in DFSP. Acanthosis is sometimes identified in the latter tumor, but it has a different configuration from that of dermatofibroma; elongation of rete ridges and a lack of basilar hypermelanosis are more often encountered in DFSP. Hemorrhage, lipidization, hemosiderin deposition, and formation of Touton-like giant cells are characteristic of dermatofibroma and can be diagnostic when present. The subcutaneous growth pattern for dermatofibroma is different from that of DFSP because dermatofibromas tend to show vertical growth along septa or rounded, ‘pushing’ protrusions into the subcutis rather than the honeycomb or horizontally layered configuration of DFSP. Polarizable collagen is usually identifiable in dermatofibromas but not in the stroma of DFSP. In contrast to dermatofibromas, hemosiderin is rarely present in a DFSP.⁸⁸⁷ Furthermore, a dermatofibroma is usually smaller and less cellular, with fewer mitoses than DFSP. Lesions with overlap features between dermatofibroma and DFSP have been reported as **indeterminate fibrohistiocytic lesions**.¹⁰²⁶ The tumors all had keloidal collagen, infiltration of the subcutis in a honeycomb pattern, low mitotic counts, and a dual population of CD34⁺ and factor XIIIa cells in varying proportions from tumor to tumor. A single recurrence was noted.¹⁰²⁶ The continuation of this diagnosis does not seem tenable in light of cytogenetic studies. In contrast, CD34 stains only focal areas, in a small percentage of cases, in dermatofibroma¹⁰²⁷ and some neural tumors.¹⁰²⁸ However, one study reported strong, diffuse staining in 20% of cases of dermatofibroma.¹⁰²⁹ Factor XIIIa, which stains most dermatofibromas, is only focally positive in a small number of cases of DFSP. MIB-1 is not a useful marker in distinguishing DFSP from dermatofibroma;¹⁰³⁰ nor is CD117, which is negative in both DFSP and cellular dermatofibromas.¹⁰³¹ Low-affinity nerve growth factor receptor (p75) is present in 95% of cases of DFSP but not in dermatofibromas.¹⁰³² Whereas stromelysin-3 is expressed in all cases of dermatofibroma, it is present in less than 10% of DFSPs.⁸²⁰ It was absent from all cases of DFSP in one study.¹⁰³³ CD163, a hemoglobin scavenger receptor, was present in 17 of 19 dermatofibromas, 23 of 23 cellular fibrous histiocytomas, but only 3 of 18 DFSPs.⁸¹⁹ CD44 was expressed strongly in all cases of dermatofibroma in one study but only weakly or not at all in DFSP.¹⁰³⁴ Whereas 96% of dermatofibromas expressed HMGA1 and HMGA2, only a small number of cases of DFSP expressed these proteins.¹⁰³⁵ Transforming growth factor- β (TGF- β) receptors are expressed much less in DFSP than in dermatofibroma.¹⁰³⁶ APO-D staining is strong in DFSP and neural tumors but negative in dermatofibromas.¹⁰³⁷ Cyclooxygenase-2 is expressed in both dermatofibromas and DFSP.¹⁰³⁸ D2-40, which recognizes a sialoglycoprotein present in a variety of tissues (including lymphatic endothelium), has been shown to be positive, with strong diffuse staining, in dermatofibromas but negative, except for faint focal stromal staining, in DFSP.⁸²² Cathepsin K, a cysteine protease with collagenolytic and elastolytic properties, is reported to be strongly expressed in dermatofibroma but absent in DFSP.⁸²³ Thrombospondin-1 (TSP-1) mediates activation of TGF- β , which may play a role in promoting sclerosis in fibrotic diseases. Expression of TSP-1 is elevated in the cells of DFSP compared to dermatofibroma.¹⁰³⁹ Collagen triple helix repeat containing-1 (Cthrc1) is a cell type-specific inhibitor of TGF- β that degrades extracellular matrix proteins and is overexpressed in certain malignant tumors. Using immunohistochemistry, Cthrc1 is positive in most cases of DFSP and is negative in most cases of dermatofibroma.⁸²¹ Fibroblast growth factors (FGFs) have also been exploited in differential diagnosis. Thus, for example, expression of FGF2/FGF4 is strongly positive in the tumor cells of dermatofibroma but negative, or only weakly positive, in DFSP.¹⁰⁴⁰ Loss of insulin growth factor-binding protein 7 (IGFBP7) has been found in the development of certain cancers; immunohistochemical staining for IGFBP7 has been negative in approximately 80% of DFSP samples and positive in more than 93% of dermatofibromas.¹⁰⁴¹ **Table 34.4**

Table 34.4 Newer immunohistochemical stains potentially useful in the differential diagnosis of DFSP and dermatofibroma

Stain	Dermatofibrosarcoma protuberans	Dermatofibroma
p75	+ (95%)	–
Stromelysin-3	– (>90%)	+
CD163	– (83%)	+ (89%)
CD44	– (negative or weak)	+
HMGA1 and HMGA2	– (most cases)	+ (96%)
TGF- β receptors	– (lesser expression)	+ (greater expression)
APO-D	+ (strong staining)	–
D2-40	– (faint stromal staining)	+
Cathepsin K	–	+
Thrombospondin-1 (TSP-1)	+ (elevated expression)	– (not elevated expression)
Cthrc1	+ (most cases)	– (most cases)
FGF2/FGF4	– (or weakly positive)	+
IGFBP7	– (80%)	+ (93%)

summarizes the newer immunohistochemical stains that may be of use in the differential diagnosis of DFSP and dermatofibroma.

DFSP of the superficial, plaque-like variety, including examples of incipient DFSP, can have a close resemblance to the **medallion-like, dermal dendrocyte hamartoma**, for which Kutzner *et al.* prefer the term ‘plaque-like CD34-positive dermal fibroma’.¹⁸ The clinical resemblances are considerable. However, superficial or patch stage DFSP involves the upper two-thirds of the dermis, with spindled cells forming horizontal tracts or fascicles, or loosely arranged in a slightly myxoid stroma, obscuring or obliterating adnexal structures, vessels, and nerves in its path, whereas plaque-like CD34⁺ dermal fibroma displays a distinct superficial band of fibroblasts (sparing the dermal papillae) and dilated venules, sparing adnexa, vessels, and nerves in the superficial dermis.¹⁸ Definitive diagnosis can be made by molecular methods, demonstrating the *COL1A1-PDGFB* gene rearrangement by RT-PCR or (particularly in formalin-fixed, paraffin-embedded tissue, due to RNA degradation) FISH analysis.¹⁸

Incomplete sampling of DFSP with myoid differentiation may lead to an erroneous diagnosis of **myofibroma**. Similar sampling errors could lead to diagnoses of **fibrosarcoma** or, less commonly, **malignant fibrous histiocytoma**; on the other hand, the finding of areas with these features in a DFSP should raise concerns that one is dealing with a sarcoma with metastatic potential. In contrast to DFSP, **neurofibromas** feature scattered small cells with buckled or S-shaped nuclei, associated nerve elements, and S100 positivity. The myxoid variant of DFSP could resemble other myxoid tumors, including myxoid liposarcoma, but its superficial location, lack of lipoblasts, and S100 negativity argue against the latter possibility. In addition, a history of recurrent tumor in this context should raise the possibility of DFSP, and a review of previous biopsy material and careful search for more characteristic cellular, storiform foci may lead to the correct diagnosis.

DFSP can resemble other CD34⁺ spindle cell tumors, including spindle cell lipoma and solitary fibrous tumor. Distinguishing features of spindle cell lipoma include relatively low cellularity, ropey or wiry collagen bundles, the absence of ectatic or hyalinized vessels, and the presence of mast cells.¹⁰⁴² The similarity between DFSP and solitary fibrous tumor can be striking, especially in superficial biopsy specimens. Adnexal entrapment is a feature that characterizes DFSP but is not seen in either solitary fibrous tumor or spindle cell lipoma. ‘Entrapped’ adipocytes can be seen in all three tumors.¹⁰⁴² Superficial

acral fibromyxoma/cellular digital fibroma is another CD34⁺ spindle cell tumor that could be potentially confused with DFSP, but the digital location, more superficial growth pattern, and apolipoprotein D negativity of spindled cells would favor a diagnosis of superficial acral fibromyxoma/cellular digital fibroma.

ATYPICAL FIBROXANTHOMA

'Atypical fibroxanthoma' (AFX) is the term coined by Helwig for a cutaneous tumor with marked cellular pleomorphism but with a course that is usually benign.¹⁰⁴³ As such, it has been regarded as one of the so-called 'pseudomalignancies' of the skin.¹⁰⁴⁴ This view must be modified somewhat in light of rare reports of metastasis (see later). Similar cases were reported at approximately the same time as those of Helwig, under several different names.^{1045,1046} The tumors usually occur as a solitary, gray to pink or red nodule, often dome-shaped, on the head or neck of the elderly.^{1047,1048} There is a rare plaque form.¹⁰⁴⁹ In some series, there has been a predominance in males.^{1049,1050} They may develop quickly, but they are usually less than 2 cm in diameter. Another clinical variant occurs in younger patients, and these lesions may be larger, more slowly growing, and with a predilection for the trunk and extremities.^{1048,1051,1052} AFX has been reported in children with xeroderma pigmentosum^{1053,1054} and, rarely, in children without this condition.¹⁰⁵⁵ In both groups, the lesions may be ulcerated and bleed. It has also arisen in an area of syringocystadenoma papilliferum associated with nevus sebaceus (organoid nevus).¹⁰⁵⁶

The nature of AFX is speculative. It has been regarded as a proliferative mesenchymal, possibly fibrohistiocytic, response to a variety of cutaneous injuries.¹⁰⁵⁷ The diversity of immunoperoxidase markers raises the possibility of heterogeneous, bimodal 'fibrohistiocytic' and 'myofibroblastic' phenotypes.¹⁰⁵⁸ In older patients, there is often a history of prolonged actinic exposure, but lesions may also develop at sites of irradiation and even trauma.¹⁰⁵⁹ This tumor may also develop in renal transplant recipients.¹⁰⁶⁰⁻¹⁰⁶² It has been suggested that there is a close relationship to MFH and that it is merely the small size and dermal location of most cases of atypical fibroxanthoma that lead to its benign behavior.^{1063,1064} A more likely explanation for these differences in behavior is the absence of *ras* oncogene mutations in AFX, whereas MFH has both H- and K-*ras* gene mutations.^{1065,1066} Whereas the large atypical cells in AFX are aneuploid, as they are in MFH, the smaller spindle-shaped cells in AFX are diploid.^{1067,1068} These theories will need reconsideration in light of the 'breakup' of MFH as an entity. Using PCR methodology and direct DNA sequencing, the Merkel cell polyomavirus (MCPyV) was detected in 4 of 23 cases of atypical fibroxanthoma.¹⁰⁶⁹

Recurrences develop in approximately 5% of cases, but in most instances, this is due to incomplete removal. Extension into subcutaneous fat is another marker for local recurrence.¹⁰⁷⁰ Lesions may even regress spontaneously or after incomplete removal. The diagnosis of AFX has been questioned in cases that have behaved aggressively.¹⁰⁷¹ There is no doubt that AFX, as reported in the past, was a heterogeneous entity that included cases of malignant melanoma and the spindle cell variant of squamous cell carcinoma.^{1072,1073} The advent of immunoperoxidase markers, and the wider use of electron microscopy, should allow more accurate assessment and diagnosis of these tumors in the future. More than 20 cases of AFX with metastases have now been reported, and several of these have been studied with immunoperoxidase or electron microscopy to exclude melanoma and squamous cell carcinoma.^{1057,1074-1076} The cases reported have tended to metastasize to regional lymph nodes,¹⁰⁵⁷ but more widespread systemic spread has been reported.¹⁰⁷⁷

The author's personal (anecdotal) experience with more than 300 cases may be of interest. The tumor is usually histologically distinctive with its bizarre cells, numerous mitoses, level 4 extension (except for

the rare plaque form), frequent 'collarette', and usual occurrence on the ear, forehead, or bald scalp. Experience has shown that it is prudent to perform immunohistochemistry for S100 protein and keratin because melanoma and squamous cell carcinoma can produce morphological simulants. The author is not aware of any metastasis in these cases, but at least 10 have recurred. In our published series of 89 cases of AFX, no recurrences or metastases were found on follow-up, despite encountering recurrences in earlier cases.¹⁰⁴⁹ All these recurrent lesions were excised with positive or narrow margins, and there was usually subcutaneous extension. Note that most lesions were completely excised because shave excisions have not been used widely in Australia until recently.

It has been suggested that atypical fibroxanthoma is a 'myth' and yet another variant of squamous cell carcinoma.¹⁰⁷⁸ This statement has been strongly refuted by others.^{1049,1079} The majority of cases do not have adjacent actinic keratosis change, which might be expected if AFX were truly a variant of squamous cell carcinoma.¹⁰⁴⁹ Most authors with experience of numerous cases of AFX believe it is a distinct clinicopathological entity with established clinical, histological, and immunohistochemical features.¹⁰⁷⁰

AFXs should be treated by wide local excision, even though several cases in our published series did not recur, despite the presence of positive margins in the original excision specimen. Mohs technique may be of benefit in cases on the head and neck.

Histopathology¹⁰⁴⁸

AFX is usually a well-circumscribed, non-encapsulated, highly cellular tumor centered on the dermis (Fig. 34.42). It is contiguous with the epidermis or separated from it by a thin zone of collagen. Sometimes cells appear to stream out from the basal layer, and in these areas the dermoepidermal junction is not always distinct.¹⁰⁷¹ In one series, nearly half the tumors extended into the subcutaneous fat,¹⁰⁷² but most observers would regard subcutaneous extension as uncommon and an indicator of possible recurrence. The epidermis is often thin or even ulcerated, but there may be peripheral acanthosis and, occasionally, a peripheral 'collarette'.¹⁰⁴⁹

There is florid pleomorphism and polymorphism, with many atypical and often bizarre cells. There are usually admixtures of three cell types, although a *spindle cell* variant without the other two cell types has been recorded.^{733,1080} The predominant cell is a plump, spindle-shaped cell in poorly arranged fascicles. Although it may occur in an atypical fibroxanthoma,¹⁰⁴⁷ a storiform arrangement should raise the possibility that the correct diagnosis is in fact an MFH or DFSP. The spindle cells have a prominent nucleus, which is often vesicular. There is also a haphazard arrangement of large polyhedral cells in the tumor. Some have vacuolated, lipid-containing cytoplasm. A *clear cell* variant has been described (Fig. 34.43).¹⁰⁸¹⁻¹⁰⁸⁵ They do not contain glycogen.¹⁰⁸⁶ True xanthoma cells are uncommon. The third cell type is a giant cell, which may be mononucleate, multinucleate, or osteoclast-like.¹⁰⁸⁷ These cells have hyperchromatic nuclei, and mitoses, including bizarre forms, are common. The cytoplasm of these cells is often partly vacuolated. Lipid stains on frozen sections will show variable amounts of lipid, usually in the polyhedral and giant cells, with only sparse amounts in the spindle cells. Hemosiderin may also be present.

Necrosis is uncommon and is usually limited to the ulcerated surface. Large areas of necrosis should raise doubts about the diagnosis of atypical fibroxanthoma. The adnexae may be distorted by the growth of the tumor, but they are not usually destroyed.

There is usually only a very small amount of interspersed collagen, although variants with prominent fibrosis and sclerosis have been reported,^{1048,1088} and keloidal collagen has been rarely described.¹⁰⁸⁹ Foci of stromal *osteoid*¹⁰⁹⁰ or *chondroid*¹⁰⁹¹ differentiation and the presence of numerous *osteoclast-like* giant cells¹⁰⁹¹⁻¹⁰⁹⁵ are rare findings. *Pigmented* and *granular cell* variants have also been reported.¹⁰⁹⁶⁻¹¹⁰¹ The

Figure 34.42 (A) Atypical fibroxanthoma. (B) This cellular tumor is composed of spindle-shaped cells and some bizarre cells with hyperchromatic nuclei. Several mitotic figures are present. (H&E)

Figure 34.43 (A) Atypical fibroxanthoma of clear cell type. (B) A mitotic figure is present. (H&E)

various forms are listed in [Table 34.5](#). A ‘carcinosarcoma’ has been reported in which a basal cell carcinoma and a sarcomatoid AFX were present.¹¹⁰² Some tumors are richly vascular. The adjacent uninvolved dermis may show solar elastosis. Any inflammatory infiltrate is usually sparse and peripheral, although neutrophils may be abundant near an ulcerated surface.

Features that may portend a more aggressive behavior include vascular invasion (the most reliable feature), deep tissue invasion, tumor necrosis,¹⁰⁵⁷ and possibly impaired host immunity.¹⁰⁷⁴ Perineural and intraneural invasion have been reported; no recurrence occurred in these two cases, but follow-up time was extremely short in one case.¹⁰⁷⁰

Immunoperoxidase studies for α_1 -antitrypsin and α_1 -antichymotrypsin are positive in more than half of the cases.^{1051,1103} Although some S100⁺ cells may be found, these constitute only a small percentage of the cells present.^{1104,1105} A case has been reported in which the giant (multinucleated) cells expressed HMB-45 and MART-1.¹¹⁰⁶ However, S100A6 is expressed in many cases.¹¹⁰⁷ These cells may represent part of the inflammatory response. The tumor cells are reactive for vimentin, and in a few cases, scattered cells stain for factor XIIIa^{717,1108} but not usually for cytokeratin or epithelial membrane antigen.¹¹⁰⁹ Weak cytokeratin expression has been reported.¹¹¹⁰ In one study, 41% of cases stained for muscle-specific actin or smooth muscle actin, 57% expressed CD68 (a monocyte-macrophage marker), but no case expressed CD34 (other than stromal blood vessels).¹⁰⁵⁸ CD31

Osteoclastic	

sometimes stains tumor cells, as well as the stromal blood vessels.¹⁰⁵⁶ Weak positivity with CD74 (LN-2) has been reported in AFX, in contrast to the strong staining for this marker in MFH.¹¹¹¹ However, this marker has been newly investigated in a series of 14 AFX cases and 8 superficial and 65 deep MFH (undifferentiated pleomorphic sarcoma) cases; the authors were unable to demonstrate that CD74 staining is either a sensitive or a specific marker for MFH.¹¹¹² Positivity for CD99 has been reported in two-thirds or more of the cases tested.^{1113,1114} Staining is less frequent in MFH.¹¹¹⁵ It has been stated that CD99 expression is not specific for AFX, and it should have no role in its diagnosis.¹¹¹⁶ CD117 was detected in 15 of the 16 cases studied in one series.¹¹¹⁷ It also highlights stromal mast cells.^{1118,1119} It is also positive in melanoma in sun-exposed areas of the body, reducing the usefulness of this marker in AFX. Melanoma may simulate AFX in other ways, and when negative for S100 protein, such melanomas

Figure 34.44 Atypical fibroxanthoma. The cells stain strongly with CD10. (Immunoperoxidase stain)

can pose a diagnostic dilemma.¹¹²⁰ Gadd45, a multifunctional protein involved in the nucleotide excision repair pathways and cell cycle checkpoint control, is expressed in some cases of AFX, MFH, and leiomyosarcomas.¹⁰⁶⁶ It has little use in diagnosis.

Strong staining with CD10 is found in most cases of AFX.^{1049,1121,1122} It is also positive in most cases of MFH and dermatofibroma and also in some cases of leiomyosarcoma. Weak staining has been reported in some melanomas and squamous cell carcinomas,¹¹²¹ but in the author's experience, CD10 remains a useful antibody, when used in a panel of antibodies for spindle and pleomorphic tumors of the skin (Fig. 34.44).

Procollagen 1 (PC1) is expressed in most cases of AFX.¹¹²³ The combination of CD10 and PC1 is a useful adjunct in an immunoperoxidase panel for the diagnosis of AFX.¹¹²⁴

Electron microscopy

The spindle cells have abundant rough endoplasmic reticulum, small vesicles and cytoplasmic filaments, and surface indentations in the nuclei.¹¹²⁵ These features suggest a fibroblastic or myofibroblastic origin. The large cells have a histiocytic appearance with lipid vacuoles.¹¹²⁶ Transition forms between these two cell types have been noted, as have histiocytic cells with Langerhans granules.^{1104,1127}

Differential diagnosis

The clinicopathologic features of AFX are relatively unique, but the differential diagnosis includes malignant melanoma, especially of the spindle cell or desmoplastic type, and spindle cell squamous cell carcinoma (SC-SCC). An absence of junctional nesting argues against melanoma, although unquestionably some desmoplastic melanomas also lack junctional changes. Immunohistochemistry is usually decisive because the cells of AFX are negative for S100 and HMB-45. However, both aberrant Melan-A and MART-1 expression have been reported as unusual findings in both AFX and MFH (undifferentiated pleomorphic sarcoma).¹¹²⁸ Other useful stains in this regard include p75 (common in melanoma, only rarely positive in AFX) and D2-40 (podoplanin), positive in approximately 50% of AFX lesions but negative in melanoma.¹¹²⁹ SC-SCC can be easily confused with AFX; in fact, prior to the advent of immunohistochemistry, there was some thought that AFX might represent a variant of SC-SCC. Unequivocal evidence for epidermal origin is not always present in SC-SCC, and differentiation from AFX then requires immunohistochemistry or

electron microscopy because the cells of SC-SCCs are usually positive for keratin and possess desmosomes and tonofilaments. The marker p63 may also be useful in distinguishing those squamous cell carcinomas with weak or negative keratin expression from AFX, although it may not be highly sensitive in SC-SCC. There is evidence that squamous cell carcinomas are capable of undergoing metaplasia to a tumor with mesenchymal characteristics, and conceivably AFX could represent a completely dedifferentiated example of this phenomenon. Leiomyosarcoma can be confused with AFX, particularly with the nonpleomorphic variant, but the latter tumor is negative for desmin and shows only focal actin positivity. Angiosarcomas with spindle cell features can also resemble AFX but can be recognized when there is evidence for primitive vessel formation. Although staining for CD31 or D2-40 could be helpful in diagnosing angiosarcoma, focal CD31 expression has been reported in AFX, and as noted previously, D2-40 expression in AFX would not be unusual. However, D2-40 expression in AFX, when positive, is frequently weak, and it can be supplemented by staining for Fli-1, a nuclear stain for vascular endothelium that highlights most cases of angiosarcoma and only a minority of cases of AFX.¹¹³⁰ The morphologic and immunohistochemical resemblance of AFX to MFH has suggested to many that AFX represents a superficial variant of that soft tissue sarcoma, with its more favorable prognosis being related to its small size, earlier detection, and responsiveness to complete excision. Reports of metastasizing AFX lend further support to this relationship. Several papers have reported in-depth comparisons of the two tumors using DNA analysis and measures of proliferative activity. One study found that 13 of 14 cases of AFX were diploid by flow cytometric analysis, whereas the literature has indicated that most cases of MFH are aneuploid. However, Michie and colleagues, using an image analysis method, concluded that AFX and MFH are indistinguishable by DNA content analysis.¹⁰⁶⁷ Oshiro and associates also demonstrated considerable overlap of the two tumors in terms of proliferative activity and p53 positivity, and they noted an aneuploid pattern in only 42% of cases of MFH.¹¹³¹ Thus, currently, most evidence favors a close relationship between AFX and MFH.¹¹³² As noted previously, strong CD10 staining is seen in most cases of AFX but can also be seen in dermatofibroma, MFH, and leiomyosarcoma, and weak staining can also be encountered in melanoma and squamous cell carcinoma. A recent study found that CD10 expression is also seen in myxofibrosarcoma (formerly myxoid MFH, which can occasionally be found in skin) and dermatofibrosarcoma protuberans.¹¹³³

ANGIOMATOID FIBROUS HISTIOCYTOMA

Angiomatoid fibrous histiocytoma is a rare soft tissue neoplasm first described by Enzinger in 1979.¹¹³⁴ It occurs predominantly on the extremities of children and young adults.¹¹³⁵ It was included for many years as a variant of MFH despite its more superficial location, the younger age of the patients, and its favorable prognosis.^{1136–1138} It is now recognized as a distinct entity.

The lesions are generally small, measuring 2–4 cm in largest diameter. Most cases behave in a relatively indolent manner, although rare metastases have been recorded.¹¹³⁹ It is regarded as a tumor of intermediate biologic behavior.¹¹³⁶

Two specific translocations have been demonstrated: t(12;16)(q13;p11) and t(12;22)(q13;q12). The first mentioned involves fusion of the *FUS* and *ATF-1* genes, and the second involves the fusion of the *EWSR1* gene with *ATF-1*.^{1136,1140} Sometimes the fusion transcript is not identified.¹¹⁴¹ The first mentioned translocation is also seen in myxoid liposarcoma, although it involves the *FUS* and *DDIT3* (*CHOP*) genes.¹¹³⁶ The *EWSR1/ATF-1* fusion product is also seen in clear cell sarcoma.^{1142–1145} The histogenesis of this tumor is uncertain. An origin from fibroblastic reticulum cells has been suggested.¹¹³⁶

Histopathology

This tumor is usually well demarcated with a thick fibrous capsule that may contain inflammatory cells. It tends to involve the subcutis.¹¹³⁴ There are large blood-filled cystic spaces and areas of hemorrhage in addition to solid nests of spindle and ovoid cells.^{1134,1146} Xanthoma cells, siderophages, and giant cells are often present. A peripheral lymphoplasmacytic infiltrate is present to some degree in approximately 80% of cases.¹¹⁴⁷ The cells show intermediate staining for CD34.^{1148,1149} Approximately 50% of cases show positivity for desmin, EMA, and CD99.^{1147,1150}

MALIGNANT FIBROUS HISTIOCYTOMA (PLEOMORPHIC UNDIFFERENTIATED SARCOMA)

MFH, formerly the most common soft tissue sarcoma of late adult life, is a controversial entity that is currently undergoing a systematic breakup into several entities, leaving behind the pleomorphic variant as a wastebasket of undifferentiated sarcomas.^{1151,1152} In fact, for a considerable period of time there have been rotating wastebaskets into which the diagnostic dilemmas of soft tissue tumors have been placed. This is not a criticism of those pathologists working in the area, who have kept us well informed, but rather an acknowledgment of the complex histogenesis of many of these tumors, which have remained an enigma despite advances in electron microscopy and then in immunohistochemistry. Some of these tumors are being revealed at last, under the surveillance of cytogenetics.

The *angiomatoid variant* of MFH is now classified as angiomatoid fibrous histiocytoma (discussed previously) on the basis of its better prognosis, its more superficial location, and its occurrence in younger individuals than those with pleomorphic MFH.

The *myxoid variant* of MFH has been reclassified as myxofibrosarcoma (see p. 988) on the basis of its distinctive and consistent clinicopathological features, most notably the presence of prominent myxoid foci comprising nearly 50% of the tumor.^{590,592,595}

The *giant cell variant*, which was not consistently included as a variant of MFH, is now regarded as a distinct entity – the giant cell tumor of soft tissues (see p. 1006). It is exceedingly rare and has morphological similarities to the bone tumor of the same name.

The *inflammatory variant* remains, for the present, in the category of MFH. Some cases probably represent undifferentiated liposarcomas. Cytogenetic studies will undoubtedly lead to a reclassification of some of the tumors in this group.

The *pleomorphic* MFH, also called pleomorphic undifferentiated sarcoma, remains largely ‘unscathed’. It is a surprisingly large group, if the findings of the Scandinavian Sarcoma Pathology Review Group are in any way representative of the situation in other countries.¹¹⁵³ Fletcher, on the other hand, believes this entity will eventually be dropped.¹¹⁵¹ The account that follows refers to the pleomorphic variant, although some of the references given include cases now reclassified into other groups.

Pleomorphic MFH usually involves the deep soft tissues and striated muscles of the proximal part of the extremities, particularly the lower.¹¹⁵⁴ The retroperitoneum is another favored site.^{973,1155} Up to 20% of cases may arise in the subcutaneous tissues, although less than 10% are confined to the subcutis without underlying fascial involvement.^{1155–1158} Cutaneous tumors are even rarer.^{1159,1160} They usually extend into subcutis and deeper structures.^{1161,1162} Adults between the ages of 50 and 70 years are most often affected. There are usually no predisposing factors but, rarely, cases have followed radiotherapy^{1156,1163} or developed at the site of a chronic ulcer,¹¹⁶⁴ osteomyelitis,¹¹⁶⁵ vaccination scar,¹¹⁶⁶ or burn scar.¹¹⁶⁷ MFH has also developed in HIV-positive patients¹¹⁶⁸ and in a renal transplant recipient.¹¹⁶²

The tumors are multilobulated, often circumscribed, gray-white fleshy masses.¹¹⁵⁶ The majority are 5 cm or more in diameter. Focal areas of hemorrhage and necrosis are quite common. The inflammatory variant may be yellow in color.

The prognosis is generally poor, with 5-year survival ranging from 15 to 30%;¹¹⁶⁹ relatively recent studies have recorded much-improved survival rates.¹¹⁷⁰ Tumors that are small and superficially located have a better prognosis than large, deep ones.^{1155,1171,1172} Tumor size, local tumor recurrence, and necrosis are associated with a greater risk of metastasis.¹¹⁵³ Proliferative activity (MIB-1 index) is not an independent prognostic parameter, despite being so in other soft tissue sarcomas.¹¹⁷³ Tumor vascular endothelial growth factor (VEGF) expression correlates with stage, grade, and prognosis in soft tissue sarcomas in general.¹¹⁷⁴ Proximal deep tumors and those in the retroperitoneum have a poor prognosis. Local recurrence and metastases are common, with the lungs and regional lymph nodes most often affected.¹¹⁵⁵

The histogenesis of this tumor has been controversial. The tumor cells show partial fibroblastic and histiocytic differentiation, as reflected by collagen production and the presence of cells that may be immunoreactive for the histiocytic markers, as well as showing occasional phagocytosis.¹¹⁷⁵ Others believe that there are no histiocytic features. It may be derived from a poorly defined mesenchymal cell, which may differentiate along histiocytic and fibroblastic lines.^{1176–1178}

Multiple structural and numerical aberrations in many chromosomes have been found in this tumor.¹¹⁷⁹ It appears that genes involved in the RB1- and TP53-associated cell cycle regulatory pathways may play a prominent role in the development of malignant fibrous histiocytoma.¹¹⁸⁰

Wide surgical resection is usually recommended for this tumor.^{1161,1170} Radiotherapy and chemotherapy have generally been used as adjunctive or palliative measures, but chemotherapy appears to have marginal efficacy.¹¹⁸¹ There is increasing use of preoperative neoadjuvant treatments such as chemotherapy, radiotherapy, hyperthermia, or a combination of these methods for high-grade soft tissue sarcomas. Although some tumors show a good response to these combined-modality treatments, the prognosis is still poor.¹¹⁸²

Histopathology

All tumors usually have an infiltrative margin. They may show areas of hemorrhage and necrosis, particularly the larger tumors. Chronic inflammatory cells are usually present throughout the tumor, particularly at the periphery. The pleomorphic tumors are now synonymous with MFH, if the inflammatory lesions are excluded.

They are composed of an admixture of plump spindle-shaped cells, clusters or sheets of histiocytes, and scattered pleomorphic multinucleate giant cells (Fig. 34.45).^{1155,1156,1183} Mitoses are common. The spindle cells may be arranged in whorls or have a storiform appearance. There is usually a delicate collagenous stroma, which in some areas may be more prominent. Focal myxoid change is quite common. Rarely, metaplastic osteoid or chondroid material is formed.¹¹⁸⁴ Xanthoma cells and siderophages are sometimes present. Similar appearances can be seen in pleomorphic sarcomas presumed to be of other cell lineages.¹¹⁷⁸ For this reason, pleomorphic MFH should now be regarded as an undifferentiated pleomorphic sarcoma.

The rare *inflammatory variant*, which is most frequently retroperitoneal, has a grave prognosis. Cutaneous lesions have been reported.¹¹⁸⁵ A diffuse, and at times intense, neutrophilic infiltrate, unassociated with tissue necrosis, is present not only in the primary tumor but also in recurrences and metastases.^{1186–1189} Xanthoma cells, both bland and anaplastic, are also present. A storiform fibrous pattern is usually seen in some areas of the tumor.¹¹⁸⁶ As stated at the beginning of this section, this tumor is probably a mixture of undifferentiated sarcomas, particularly liposarcoma.

Figure 34.45 Malignant fibrous histiocytoma composed of spindle-shaped and polygonal cells and scattered pleomorphic giant cells, some of which are multinucleate. (H&E)

The tumor cells contain vimentin;^{1190,1191} cytokeratin has also been present in a few tumors.¹¹⁹² Strong staining for CD74 has been reported,¹¹¹¹ but it was not confirmed in a recent study.¹¹¹² Various histiocyte markers can be demonstrated, using immunoperoxidase techniques, in 60–80% of malignant fibrous histiocytomas. Those used have included α_1 -antitrypsin and α_1 -antichymotrypsin.⁷⁹⁸ CD68 and CD10 are frequently positive, whereas CD34 is negative.^{1137,1138,1193} Rare cases with S100 expression have been reported.¹¹⁹⁴

Electron microscopy¹¹⁹⁵

Studies have consistently shown cells with fibroblastic and histiocytic morphology, as well as undifferentiated mesenchymal cells with a narrow rim of cytoplasm and scattered ribosomes.^{1176,1196} Myofibroblasts were said to be the predominant cell in one case.¹¹⁹⁷

GIANT CELL TUMOR OF SOFT TISSUE

Primary giant cell tumor (osteoclastoma) of soft tissues is a rare tumor that may arise in both superficial and deep soft tissues.^{1151,1198–1201} It is found predominantly on the thighs, trunk, and upper extremities. It occurs in a broad age range.¹²⁰¹ There is no sex predilection. Morphologically, it has some resemblance to giant cell tumor of bone. Cases involving the dermis, but also extending into the subcutaneous fat, have been reported.^{1199,1202} Although no recurrences had occurred at the time of publication of these cases, the follow-up period was brief. Metastases have been rare in cases having a deeper location.¹²⁰¹

Histopathology

There are round to spindle-shaped cells forming the stroma for uniformly scattered, osteoclast-like multinucleated giant cells (Fig. 34.46). Mitoses are not uncommon and average two or three per 10 high-power fields. Mitotic ‘hot spots’ may be present. Foci of hemorrhage, hemosiderin deposition, and foamy macrophages are usually present. Aneurysmal bone cyst-like areas may also be present. There is some fibrosis, usually at the edge.¹¹⁹⁹ The tumor cells express vimentin and CD68. The latter marker is usually strongly expressed in giant cells; it is focal in mononuclear cells.

This tumor must be distinguished from the malignant diffuse-type tenosynovial giant cell tumor, the malignant variant of tenosynovial giant cell tumor. Like its benign counterpart, it tends to occur within or near the large joints of the extremities.¹²⁰³

Figure 34.46 Giant cell tumor of soft tissue composed of numerous osteoclast-like giant cells. (H&E)

PRESUMPTIVE SYNOVIAL AND TENDON SHEATH TUMORS

FIBROMA OF TENDON SHEATH

Chung and Enzinger formally documented fibroma of tendon sheath in 1979, with a report of 138 cases.¹²⁰⁴ It is a solitary, slow-growing subcutaneous tumor with a predilection for the fingers, hands, and wrists of middle-aged adults, particularly males.^{1205,1206} Recurrences occur in approximately 20% of cases.

The fibromas are well-circumscribed, often lobulated, gray to white tumors that measure 1 or 2 cm in diameter. They are usually attached to a tendon sheath.

A (2;11) translocation has been found in some of the tumor cells in one case, suggesting that this lesion is neoplastic and not a reactive process.¹²⁰⁷

Histopathology^{1204,1208}

These tumors are situated in the subcutaneous tissue, sometimes with dermal extension. There are also pseudopods, or small foci of tumor in the surrounding connective tissue, which may in part explain the proneness to recurrence of these lesions (Fig. 34.47).¹²⁰⁹ There are relatively sparse spindle or stellate cells embedded in a dense fibrocollagenous stroma. Cellular areas are present, sometimes toward the periphery. The stroma shows variable hyalinization and sometimes has a whorled pattern with associated artifactual clefting. Myxoid degeneration and, rarely, focal calcification of the stroma may be present. A characteristic feature is the presence of dilated or slit-like vascular channels. A sparse mononuclear cell infiltrate is sometimes present at the periphery.

A rare pleomorphic variant (**pleomorphic fibroma of tendon sheath**) has been reported. There are scattered large cells with pleomorphic, hyperchromatic nuclei but no mitoses.¹²¹⁰ A further variant of pleomorphic fibroma exists: it has overlap features with the giant cell tumor of tendon sheath (see later). This has given rise to the suggestion that fibroma of tendon sheath is the end and sclerosing stage of giant cell tumor,¹²¹¹ although this has been strongly disputed.¹²¹²

Electron microscopy

Ultrastructural examination has shown the spindle cells to be myofibroblasts¹²¹³ with some fibroblasts.^{1206,1214}

Figure 34.47 Fibroma of tendon sheath. This tumor is sparsely cellular and has a somewhat hyalinized stroma. The multifocal configuration, with pseudopod formation, may explain its propensity toward recurrence. (H&E)

Differential diagnosis

The close clinical resemblance between giant cell tumor of tendon sheath and fibroma of tendon sheath, and the rare presence of giant cells in the latter, suggests that these two tumors are related. They may then simply represent different stages in the evolution of a single lesion (fibroma of tendon sheath presumably representing a later developmental stage). This concept is supported by histologic studies that have shown transitional forms between the two¹²¹¹ and by immunohistochemical studies showing evidence for macrophagic and myofibroblastic differentiation in both tumors.¹²¹⁵

GIANT CELL TUMOR OF TENDON SHEATH

Giant cell tumor of tendon sheath is a not uncommon benign tumor with a predilection for the dorsal surface of the fingers, in the vicinity of the distal interphalangeal joint.^{1216,1217} Periungual lesions are rare.¹²¹⁸ It occurs particularly in young and middle-aged adults. It is a slow-growing, usually asymptomatic lesion that may measure up to 3 cm in diameter at the time of removal. Multicentric lesions are rare.¹²¹⁹ Local recurrence, usually a result of incomplete removal, occurs in 15% of cases.¹²¹⁶ Satellite lesions were found in 80% of recurrent cases in a recent large study.¹²²⁰

Giant cell tumors are lobulated and gray-brown in color, with yellowish areas. They are usually attached to a tendon sheath or joint capsule, but cutaneous involvement can occur.^{1221,1222} The histogenesis of giant cell tumors has been controversial. They have been regarded as a variant of fibrous histiocytoma and as a tumor derived from mesenchymal cells.¹²²³ One study concluded that the cells are of monocyte-macrophage lineage, closely resembling osteoclasts.¹²²⁴ The immunophenotype (see later) is more suggestive of a synovial cell origin.¹²²⁴ It appears to be a polyclonal proliferation.¹²²⁵

This tumor must be distinguished from the **giant cell tumor of soft tissue**, a rare tumor resembling the lesion of bone (see p. 1006).

Histopathology^{1216,1226}

The lesion has an eosinophilic collagenous stroma with variable cellularity. In the sparsely cellular areas, the cells are plump and spindle shaped, set in a partly hyalinized stroma, whereas in the more cellular

areas the cells are usually polygonal. Small clusters of lipid-laden histiocytes are often present. Multinucleate giant cells with up to 60 or more nuclei are a characteristic feature (Fig. 34.48). They are variable in number and haphazardly distributed. Hemosiderin is invariably present, and sometimes there are cholesterol clefts.

The proliferating mononuclear cells stain positively for CD68, HAM-56, and vimentin but not for S100, cytokeratins, EMA, CD45, CD34, desmin, or smooth muscle actin.¹²¹² The giant cells stain for CD68, vimentin, and CD45.¹²¹²

Electron microscopy

Ultrastructural studies have usually supported a synovial or fibrohistiocytic origin,¹²²⁷ although another report documented a pleomorphic cell population in which the giant cells had some similarity to osteoclasts and the stromal cells similarities to primitive mesenchymal cells, osteoblasts, fibroblasts, and histiocytes.¹²²³

EPITHELIOID SARCOMA

Epithelioid sarcoma, first delineated by Enzinger,¹²²⁸ is a rare aggressive tumor that usually involves the deep subcutis and underlying soft tissues. Infrequently, it arises in the dermis and superficial subcutis, where it may be confused both clinically¹²²⁹ and histologically with various benign cutaneous diseases, including granuloma annulare.^{1230,1231} It has a predilection for the extremities, particularly the hands, of young adult males.^{1232–1234} Childhood cases occur.¹²³⁵ Lesions of the face,¹²³⁶ vulva,¹²³⁷ and penis¹²³⁸ have also been described. A history of trauma is sometimes given.¹²³² A case has been reported in a patient with neurofibromatosis type 2.¹²³⁹

It presents as one or more slow-growing tan-white nodules with an indistinct infiltrating margin. Ulceration develops late, if at all. Local recurrence occurs in nearly 80% of cases, and metastases occur in 30–45%.^{1232,1240–1242} The regional lymph nodes and lungs are the most common initial sites of metastases. The skin of the scalp represents another common site of distant metastasis.¹²⁴³ The tongue is one of several rare metastatic destinations.¹²⁴⁴ Adverse prognostic features are older age, a proximal or axial location, tumor size greater than 5 cm, deep extension, necrosis, rhabdoid cytomorphology, vascular invasion, incomplete excision, metastases, and numerous mitotic figures.^{1232,1245,1246}

Epithelioid sarcoma is of disputed histogenesis. A synovial origin, which was favored at one time,^{1247,1248} now seems unlikely.¹²⁴⁶ A histiocytic, fibroblastic,¹²⁴⁹ myofibroblastic,¹²⁵⁰ perineurial,¹²⁵¹ and mesenchymal reserve cell¹²⁵² origin have all been suggested. One tumor produced granulocyte colony-stimulating factor, but it is difficult to draw any histogenetic conclusions.¹²⁵³ An *N-ras* oncogene mutation was demonstrated in the tumor cells in one study.¹²⁴¹ In another, allelic loss on chromosome 22q was present in 60% of cases.¹²⁵⁴ Subsequent studies have shown chromosomal gains at 22q and other sites,¹²⁵⁵ but there are no consistent or specific chromosomal rearrangements or changes.¹²⁵⁶

Fletcher and colleagues have drawn attention to an aggressive tumor with epithelioid and rhabdoid features, which they have called 'proximal-type' epithelioid sarcoma.¹²⁵⁷ Most of the cases involved the deep soft tissues in axial proximal locations, but several, in the region of the vulva, involved the subcutis. It usually occurs in middle-aged or older adults,¹²⁵⁶ but cases in children have been reported.¹²⁵⁸ It recurs more frequently and metastasizes earlier than the classic type.¹²⁵⁹

SMARCB1/INI1 gene inactivation and loss of tumor suppressor *SMARCB1* protein expression have been reported in cases of epithelioid sarcoma.¹²⁶⁰ Alterations in this gene were first described in malignant rhabdoid tumors of the kidney¹²⁶¹ and have also been found in 'proximal-type' epithelioid sarcoma.¹²⁶²

Treatment of epithelioid sarcoma of both types consists of radical surgical excision of the tumor and, if indicated, therapeutic lymph node dissection.¹²⁶³ In patients who have large tumors, isolated limb

Figure 34.48 (A) Giant cell tumor of tendon sheath. (B) This subcutaneous tumor is composed of polygonal cells and collections of multinucleated giant cells. **(C)** Another lesion displays numerous multinucleated giant cells with smudged, eosinophilic cytoplasm. (H&E)

Figure 34.49 (A) Epithelioid cell sarcoma. (B) There are sheets of epithelioid and polygonal cells. (H&E)

perfusion with tumor necrosis factor and melphalan may be useful.¹²⁶³ The role of postoperative radiotherapy after wide surgical excision needs further research. Its use is usually confined to cases with positive surgical margins.¹²⁶⁴ Sentinel lymph node biopsy has also been suggested as a useful procedure.¹²⁶³

Histopathology^{1230,1232}

The low-power appearance often resembles a necrobiotic or granulomatous process or an epithelial tumor. Epithelioid sarcoma is an ill-defined cellular lesion forming vague nodules in the dermis and subcutis. There is subtle extension into the contiguous fascial and tendinous structures. Perineural invasion is present in approximately 20% of cases.¹²⁴⁵ The tumor is composed of oval to polygonal cells with abundant, often eosinophilic, cytoplasm and a gradual transition to plump spindle cells (**Fig. 34.49**).^{1265,1266} Rarely, a spindle cell pattern predominates.¹²⁶⁷ Nuclear pleomorphism and scattered mitoses are present. Multinucleated giant cells are rare or absent. Sometimes the pattern can look deceptively bland.¹²⁶⁸

A characteristic feature is the presence of central necrosis (geographic necrosis) or fibrosis. Collagen also extends between the cells. Calcification is present in approximately 20% of cases, and osseous metaplasia is present in 10%.¹²³² Hemosiderin is often present. A case with angiomatoid features has been reported.¹²⁶⁹ A perinodular

inflammatory cell infiltrate of lymphocytes and histiocytes is a usual feature.¹²⁷⁰

The ‘proximal-type’ variant grows in a multinodular pattern and shows prominent epithelioid and rhabdoid features. It lacks a granuloma-like pattern. There is marked cytological atypia. The cells are positive for vimentin, cytokeratin, and EMA. Some tumors express desmin and CD34.¹²⁵⁷ This variant of epithelioid sarcoma needs to be distinguished from extrarenal malignant rhabdoid tumor (see p. 1038), an ‘entity’ that undoubtedly includes many cases of proximal-type epithelioid sarcoma.¹²⁵⁸

Immunoperoxidase studies of the usual (classic) type show that many tumor cells contain cytokeratin, EMA, and vimentin but not CD45, S100 protein, desmin, FLI-1, and CK20.^{1246,1271–1275} The combination of cytokeratin, EMA, and vimentin positivity is a characteristic feature of this tumor, although exceptions occur (Fig. 34.50).¹²⁷⁶ CAM5.2 is a useful marker for detecting the cytokeratins that are usually present.¹²⁷⁵ Cytokeratin 5/6 is found in only rare cells in epithelioid sarcoma, in contrast to spindled squamous cell carcinoma in which it is diffusely positive.¹²⁷⁷ Nearly all epithelioid sarcomas express cytokeratin 8 (CK8), whereas approximately 75% express CK19.¹²⁷⁸ Patchy membrane staining for CD34 and more diffuse staining for muscle-specific actin¹²⁷⁸ occur in more than half of the cases.¹²⁷⁶ Most cells express vascular–endothelial cadherin.¹²⁷⁹ Histiocytic markers have usually been negative.¹²⁹⁰ Immunohistochemistry for SMARCB1 is negative in epithelioid sarcoma, and multiplex ligation-dependent probe amplification for detection of deletions of SMARCB1 can be performed on formalin-fixed, paraffin-embedded tissue.¹²⁶¹

Electron microscopy

Light and dark cells are present within the tumor cell population. There are many filopodia-like surface extensions of cytoplasm,¹²⁴⁷ and there are bundles of intermediate filaments in the cytoplasm.¹²⁷³ Occasional pseudoglandular spaces have been present in some tumors.¹²⁴⁸ In summary, there are epithelial and mesenchymal features, including myofibroblastic differentiation.¹²⁴⁶

Differential diagnosis

A major problem in differential diagnosis is the confusion of superficial forms of epithelioid sarcoma with inflammatory processes, especially necrobiotic granulomas such as granuloma annulare. Careful attention to the cells comprising the lesion is worthwhile because those of epithelioid sarcoma have an atypical, immature appearance and often deeply staining eosinophilic cytoplasm. Immunohistochemistry can also be of great help because unlike the cells of necrobiotic granulomas, the tumor cells of epithelioid sarcoma are positive for keratin and epithelial membrane antigen. Conversely, within this differential diagnosis, only the cells of necrobiotic granulomas stain positively for leukocyte common antigen.¹²⁷² The distinctive configuration and staining of these lesions helps in separating epithelioid sarcomas from other soft tissue sarcomas and malignant melanoma. The CD34 staining that is sometimes demonstrable in epithelioid sarcoma has been proposed as a means of distinguishing this from metastatic carcinoma or from malignant rhabdoid tumor.¹²⁷⁸ Dysadherin expression is also significantly higher in epithelioid sarcoma than in malignant rhabdoid tumor.¹²⁸⁰ There is a variant of hemangioendothelioma, termed pseudomyogenic hemangioendothelioma, that closely resembles epithelioid sarcoma. It occurs in soft tissue and bone, tends to involve the lower extremities, and is multicentric although generally indolent, with rare metastasis.¹²⁸¹ It shows keratin positivity (AE1/3, not MNF116), weak CD31 positivity, and expression of ERG (transcription factor, a marker of vascular endothelial tumors), but in contrast to many epithelioid sarcomas, it is CD34[−]. No loss of INI-1 expression was noted in the study of Amary *et al.*¹²⁸² (See the following section for differentiation from synovial sarcoma.)

Figure 34.50 (A) Epithelioid sarcoma. (B) The tumor cells are quite pleomorphic. The inset shows positive staining for EMA. (H&E and immunoperoxidase inset)

SYNOVIAL SARCOMA

Only brief mention is made of this soft tissue sarcoma, which has a predilection for the extremities of young and middle-aged adults. It exhibits a wide spectrum of biological behavior. The high-risk group includes older patients,¹²⁸³ tumor size greater than 5 cm, and poor differentiation.^{1284,1285}

Only one case of superficial synovial sarcoma involving the dermis has been reported.¹²⁸⁶ It involved the skin overlying the knee in a young woman. It recurred six times during a 24-year period.¹²⁸⁶

A study of 21 minute synovial sarcomas of the soft tissues of the hands and feet was reported from the AFIP in 2006.¹²⁸⁷ All lesions were less than 1 cm in diameter. The median age of the affected patients

was 29 years (range, 8–60 years).¹²⁸⁷ SYT–SSX fusion transcripts were demonstrated in five cases. Minute tumors appear to have a favorable outcome if completely excised.¹²⁸⁷ Genomic deletion of p16^{INK4A} (CDKN2A) is a frequent genetic event in synovial sarcomas.¹²⁸⁸

The chromosomal translocation t(X;18) has been described in 90% of synovial sarcomas, and the presence of SYT–SSX fusion products is quite characteristic.^{1289,1290} Usually, the proximal portion of the SYT gene at chromosome 18q11 is fused to the distal portion of one of several duplicated SSX genes at chromosome Xp11.¹²⁹¹ SYT/SSX1 translocations are nearly three times more frequent than SYT/SSX2 translocations, and this latter pattern is usually associated with monophasic tumors.¹²⁹¹

In general, aggressive treatment has been advocated for synovial sarcomas; in earlier times, this often meant amputations. Postoperative radiation is usually used after conservative excisions, but its efficacy has been questioned.¹²⁸⁷ Chemotherapy is used for large, inoperable, and recurrent tumors, but it does not seem necessary for the minute variants.¹²⁸⁷ It is often used in children with synovial sarcoma.¹²⁹² Because some tumors express EGFRs and HER-2/*neu* protein, treatment with tyrosine kinase inhibitors has been suggested as a future alternative treatment modality.¹²⁹¹

Histopathology

Synovial sarcoma occurs in two predominant patterns: a monophasic form composed of spindle cells, sometimes in a fascicular pattern, and a biphasic form with spindle cells admixed with glandular structures of varying size (Fig. 34.51). The minute lesions (discussed above) were biphasic in 7 cases and monophasic in 14. Microscopic calcification was present in 8 cases.¹²⁸⁷ The biphasic lesions usually stain for cytokeratin and EMA, whereas approximately 70% of the monophasic form stain for at least one of the cytokeratins or EMA.^{1284,1293} Focal staining for S100 protein is seen in approximately 25% of cases.¹²⁹⁴ MMP-2 expression correlates with epithelial differentiation in synovial sarcomas.¹²⁹⁵

The cutaneous lesion (discussed above) was composed predominantly of spindle cells with scattered epithelial nests. Focal myxoid and hemangiopericytoma areas were present.¹²⁸⁶ The spindle cells stained for vimentin, CAM5.2, and EMA.¹²⁸⁶

Differential diagnosis

Synovial sarcomas must be differentiated from other spindle cell sarcomas and occasionally from adnexal or metastatic carcinomas. A microscopic resemblance to epithelioid sarcoma is also possible, and staining reactions of the two tumors are similar. Differences include their usual clinical locations (epithelioid sarcoma is more likely to involve the forearm and hand and to show dermal involvement), cell arrangements (epithelioid sarcoma features nodular aggregates of tumor cells, sometimes with central zones of necrosis), and the deeply eosinophilic cytoplasm characteristic of the polygonal cells of epithelioid sarcoma.

MISCELLANEOUS ENTITIES

The miscellaneous group of disorders includes several very rare entities in which fibrous tissue forms a significant component and also another group with a myxoid stroma. Collagenous papules of the ear are no longer considered in this chapter. They result from the deposition of amyloid in the papillary dermis (see p. 437).^{1296–1298}

FIBRO-OSSEOUS PSEUDOTUMOR OF THE DIGITS

Fibro-osseous pseudotumor is a rare tumor of the subcutaneous and soft tissues of the digits, usually in young adults.^{1299,1300} There is a close

Figure 34.51 Synovial sarcoma. (A) Spindle cells of a synovial sarcoma. (B) Nests and cords of epithelial cells. (H&E)

histological resemblance to myositis ossificans, with osteoid formation and a background stroma of fibroblasts, collagen, and myxoid material.^{1299,1301} The lesion usually involves the subcutis and has an irregular multinodular growth pattern,¹²⁹⁹ without the well-developed zonal arrangement characteristic of myositis ossificans. Mitotic activity is noted within the areas of fibroblast proliferation. The fibroblast-like cells stain positively for vimentin and smooth muscle actin and are negative for keratin, CD34, factor VIII, and S100. The results favor myofibroblastic differentiation,¹³⁰² although actin staining was negative and no dense bodies were found ultrastructurally in one study.¹³⁰¹

OSSIFYING FIBROMYXOID TUMOR

Ossifying fibromyxoid tumor is a rare tumor of soft tissues of intermediate malignant potential that sometimes involves the subcutaneous tissue.^{1303–1306} Dermal involvement is exceedingly rare.¹³⁰⁷ It occurs preferentially on the upper and lower extremities and, rarely, in the head and neck region. It has also presented as a scalp cyst.¹³⁰⁸ There is a male predominance. The tumors measure 1–14 cm in diameter (median, 4 cm).¹³⁰⁹

Ossifying fibromyxoid tumor was initially thought to be of neural origin, but it seems more likely that it is derived from mesenchymal stem cells that also express neural differentiation, which is often weak but occasionally quite prominent.¹³⁰⁷ Genomic analysis of malignant tumors has shown a clonal pattern but no consistent chromosomal abnormality.¹³⁰⁸

In the vast majority of cases, complete surgical excision is curative, but local recurrences are common unless an adequate clearance is obtained. Mohs surgical technique has been used for this purpose.¹³⁰⁸ Metastases were recorded in 16% of patients in a series of consultation cases.¹³⁰⁹ There were no metastases in the series of 104 cases reported from the AFIP.¹³¹⁰

Histopathology

The tumor is circumscribed, with a characteristic fibrous capsule and an incomplete peripheral shell of new bone.¹³⁰⁴ Bone is not present in all cases, and its absence, particularly in a small biopsy, can lead to difficulties in diagnosis.¹³⁰⁸ Sometimes the bone is central rather than peripheral in location.¹³¹¹ There are cords, nests, and sheets of oval to round and spindle-shaped cells with a well-vascularized stroma.¹³⁰³ The stroma may be mucoid, fibromyxoid, or fibrous. The stroma stains with the colloidal iron method and also with Alcian blue (pH 1.0–2.5). The presence of high cellularity, high nuclear grade, or more than two mitotic figures/50 high-power fields may be associated with local recurrence and/or metastatic disease, whereas an infiltrative growth pattern leads to an increased risk of recurrence.¹³⁰⁹ Tumor cells stain for vimentin and show strong focal staining for S100 protein. Some cases have shown staining for desmin, smooth muscle actin, pancytokeratin, glial fibrillary acidic protein, and neuron-specific enolase.^{1309,1310}

Electron microscopy

In one report of cutaneous cases, the spindle and polygonal cells showed abundant intermediate filaments in their cytoplasm.¹³⁰⁷ In addition, foci of partial duplication of the external lamina were noted in one of the two cases studied.¹³⁰⁷

FIBROADENOMA

Fibroadenomas resembling those seen in the breast may arise along the embryonic milk line and elsewhere.¹³¹²

NODULAR FIBROSIS IN ELEPHANTIASIS

Multiple nodules, sometimes large, are a common complication of nonfilarial elephantiasis of the lower legs.¹³¹³ This idiopathic condition is endemic in Ethiopia.¹³¹³ Microscopy shows bundles of collagen in the dermis, in irregular whorls, with a variable number of fibroblasts depending on the age of the lesion.¹³¹³ A few small blood vessels, some with a surrounding cuff of lymphocytes, are also present. The overlying epidermis shows pseudoepitheliomatous hyperplasia.¹³¹⁴

Discrete fibroma-like nodules have been recorded in a patient with Kaposi's sarcoma and lymphedema.¹³¹⁵

JUVENILE HYALINE FIBROMATOSIS

Juvenile hyaline fibromatosis (OMIM 228600), an exceedingly rare autosomal recessive condition, is characterized by large tumors, especially on the scalp;^{1316,1317} whitish cutaneous nodules; hypertrophy of the gingiva;¹³¹⁸ flexural contractures; and often focal bone erosion.^{380,1319–1329} Onset is in infancy and childhood. A localized form, with slow progression and no visceral involvement, has been reported.¹³³⁰ Spontaneous regression of tumors sometimes occurs.

Figure 34.52 Juvenile hyaline fibromatosis. Fibroblast-like cells are embedded in an amorphous, eosinophilic matrix. (H&E)

Recurrent infections may lead to death. It is allelic with the condition reported as infantile systemic hyalinosis (OMIM 236490).¹³³¹ Both conditions are due to mutations in the capillary morphogenesis protein 2 (CMG2) gene on chromosome 4q21. It is considered further in Chapter 14, page 444.

Histopathology^{1319–1323}

The tumor nodules are composed of a markedly thickened dermis with a vaguely chondroid appearance. They are composed of fibroblast-like cells, with abundant granular cytoplasm, embedded in an amorphous eosinophilic ground substance that is PAS positive and diastase resistant (Fig. 34.52). It does not stain with Alcian blue.¹³²⁴ The ground substance is abundant in older lesions and presumably represents a collagen precursor produced by the fibroblast-like tumor cells. Early lesions may not show the hyaline collagen changes of larger lesions of long duration.¹³³² Basophilic calcospherules are rarely present.¹³³³

Differential diagnosis

The cutaneous lesions of juvenile hyaline fibromatosis resemble those of myofibromatosis, neurofibromatosis, multiple cylindromas, or mucopolysaccharidoses. However, other clinical features (gingival hyperplasia and joint contractures) and the microscopic findings of fibroblasts within a hyaline matrix make juvenile hyaline fibromatosis unique. Lipoid proteinosis is another recessively inherited disorder characterized by cutaneous papules and nodules (with tongue and vocal cord involvement) and by deposition of amorphous, hyaline material in the dermis. However, large deforming nodules and joint contractures, as seen in juvenile hyaline fibromatosis, are not typical, and the amorphous material of lipoid proteinosis consists of glycoprotein and hyaluronic acid. In addition, lesions of lipoid proteinosis are characterized by reduplication of basement membrane material and by a lack of proliferative fibroblasts.

MULTIFOCAL FIBROSCLEROSIS

Subcutaneous fibrosis is an uncommon complication of multifocal fibrosclerosis, a condition in which progressive fibrosis of several discrete regions of the body, particularly the retroperitoneum and mediastinum, occurs.¹³³⁴ Ulceration and vasculitic lesions may also develop in the skin.

MESENCHYMAL HAMARTOMA

The designation mesenchymal hamartoma is preferred to the alternative suggestion of benign polymorphous mesenchymal tumor of soft parts. Only two cases have been reported of this benign tumor of uncertain histogenesis.¹³³⁵ It is characterized by a prominent lobular configuration with distinctive garland-shaped structures composed of cells expressing glial fibrillary acidic protein (GFAP) encased in concentric loops of fine collagen fibers. The clusters of cells are surrounded by a copious myxoid matrix. The reported lesions were located in the subcutis with no dermal extension.

PLEOMORPHIC HYALINIZING ANGIECTATIC TUMOR

The pleomorphic hyalinizing angiectatic tumor (PHAT) is a rare mesenchymal tumor of disputed histogenesis, with some features suggesting a vascular origin. More than 50 cases have now been reported, but 41 of these cases were described by Folpe and Weiss, who suggested that a precursor lesion (early PHAT, which they claim is identical to hemosiderotic fibrohistiocytic lipomatous tumor) may exist.¹³³⁶ PHAT was first described in 1996.¹³³⁷ It occurs principally in the superficial soft tissues of the distal extremities.¹³³⁸

This tumor is regarded as a mesenchymal tumor of intermediate malignancy, given its high rate of local recurrence.^{606,1336} To date, no metastases have been recorded.

Histopathology

The tumor has some resemblance to malignant fibrous histiocytoma and neurilemmoma.^{1337,1339} It features ectatic, fibrin-containing vessels with prominent circumferential hyalinization, spindled and pleomorphic stromal cells with intranuclear inclusions, and a variable inflammatory component.¹³³⁶ The lesion referred to as 'early PHAT', and similar to the lesions reported as 'hemosiderotic fibrohistiocytic lipomatous tumor', also known as 'hemosiderotic fibrolipomatous tumor',¹³⁴⁰ was composed of short fascicles of hemosiderin-stippled spindled cells that infiltrated fat and surrounded congeries of small, damaged vessels.¹³³⁶ Browne and Fletcher have disputed their relationship.¹³⁴⁰

The spindle cells stain with vimentin and CD34 but not with S100, actin, or desmin.^{1336,1338,1339} The vascular endothelial cells stain with both CD31 and CD34.¹³³⁸

PHOSPHATURIC MESENCHYMAL TUMOR

Phosphaturic mesenchymal tumor is a rare, soft tissue tumor^{1341,1342} that results in osteomalacia (oncogenic osteomalacia) as a consequence of hypophosphatemia caused by renal phosphate wasting.¹³⁴³ It results from the excretion by the tumor of fibroblast growth factor 23 (FGF23), which inhibits reabsorption of phosphate in the kidney.^{1343,1344} Removal of the tumor results in a cure of the osteomalacia.

Approximately 50% of the tumors arise in bone, and the remainder arise in soft tissues. Some may arise in the dermis and subcutaneous tissues – the reason for its inclusion here. Many tumors are small and asymptomatic (apart from the effects of the secretion product), and extensive imaging studies may be required to find the lesion.¹³⁴⁴ Elevated serum levels of FGF23 are diagnostic of this tumor.

Histopathology

Because of the wide variability in appearances, only recently has this lesion been regarded as a single histopathological entity.¹³⁴² It is char-

acterized by a nodular collection of spindle, stellate, and round-shaped cells, without atypia, that surround numerous vascular spaces. In places, the tumor has a hemangiopericytoma-like appearance, whereas in other cases or areas, the vessels have a dilated, sinusoidal configuration. There is a myxoid or myxochondroid matrix with foci of calcification associated with osteoclast-like giant cells. Bone may also be present. The tumor cells are not reactive with S100, CD34, or EMA.¹³⁴³

CUTANEOUS MYXOMA

Cutaneous myxomas are rare tumors that may be associated with a systemic syndrome – Carney's complex – which includes cardiac myxomas, spotty cutaneous pigmentation, and endocrine overactivity as its usual manifestations.^{1345,1346} At other times, myxomas are solitary tumors, usually on the digits, and unassociated with any systemic abnormalities.^{1347,1348} Cutaneous myxomas are discussed in further detail with the mucinoses (see Chapter 13, p. 417) because of their close resemblance to digital mucous cysts.

Histopathology^{1347,1348}

Cutaneous myxomas are composed of stellate and spindle-shaped cells set in a loose myxoid stroma. Basaloid proliferations resembling those seen over a dermatofibroma have been reported in some cases.¹³⁴⁹

SUPERFICIAL ACRAL FIBROMYXOMA

Superficial acral fibromyxoma was first described by Fetsch, Laskin, and Miettinen in 2001.¹³⁵⁰ They reported 31 cases. Apart from the series of 32 cases reported from the AFIP in 2008,¹³⁵¹ only a small number of cases have been reported subsequently.^{132,1352–1355} This tumor has a striking predilection for the fingers and toes and a tendency to involve the nail region.¹³⁵⁰ The heel is another site of occurrence. In the original series, the patients presented with a solitary mass, 0.6–5 cm in diameter, that had been present for months to many years. Complete excision is usually curative, but partial excision may lead to persistence/recurrence of the lesion.¹³⁵⁰ The recurrence rate of this tumor may exceed 20%.¹³⁵¹

It has been suggested that the cases reported as cellular digital fibroma (see p. 972)¹³¹ may be examples of superficial acral fibromyxoma.¹³²

Histopathology

The lesions are typically located in the dermis and/or the subcutis. They are composed of spindled and stellate-shaped cells with random, loose storiform and fascicular growth patterns.¹³⁵⁰ The cells are situated in a myxoid or collagenous stroma, often with accentuated vascularity and increased numbers of mast cells (Fig. 34.53). Mature fat cells have also been reported in the stroma.¹³⁵⁶ As mentioned previously, there is some overlap with the cases reported as cellular digital fibroma.^{131,132}

In most cases, the cells express CD34, EMA, and CD99.¹³⁵⁶ There is no immunoreactivity for actins, desmin, keratins, or HMB-45.¹³⁵⁰ Although these findings have been confirmed, in part, by some subsequent reports,^{1353,1355} others have not shown any staining for EMA and CD99.¹³⁵² These cases were also negative for S100, actin, and desmin. Both CD10 and vimentin staining have also been reported.^{1355–1357}

SUPERFICIAL ANGIOMYXOMA

Angiomyxomas are a distinct variant of myxoma that may also contain epithelial elements (see p. 417).¹³⁵⁸ They present as slow-growing, painless nodules that may involve the dermis and subcutis of any part

Figure 34.53 Superficial acral fibromyxoma. (A) Loosely organized spindled cells are randomly arranged within a partly myxoid stroma. (B) Prominent vascularity and increased numbers of mast cells can be identified. (H&E)

of the body. They may occur on the finger.¹³⁵⁴ One case was present at birth.¹³⁵⁹ They usually measure 1–5 cm in diameter, but larger variants have been recorded.¹³⁵⁸ Local recurrence may occur after surgical removal, but not metastasis.¹³⁶⁰

Histopathology¹³⁵⁸

Angiomyxomas are usually centered on the subcutis, but extension into the dermis is almost invariable. They are composed of spindle-shaped and stellate cells set in a copious, well-vascularized basophilic matrix (Fig. 34.54). Another distinguishing feature of these lesions is the presence, in more than half, of an epithelial component, which takes the form of epithelial strands or a keratin-filled cyst.¹³⁵⁸ An association with trichofolliculoma has recently been reported.¹³⁶¹

The stromal cells are positive for vimentin and (focally) CD34 but negative for S100, keratin, and desmin.^{1358,1360,1362} Smooth muscle actin staining has been negative in most studies,¹³⁶³ but a significant percentage of the cases of Fetsch *et al.* demonstrated muscle-specific actin

Figure 34.54 Superficial angiomyxoma. There is a keratinous cyst in the center of the tumor, which has a vascular and myxoid stroma. (H&E)

and smooth muscle actin positivity.¹³⁶² These same authors also found factor XIIIa positivity in approximately 50% of cases. Staining for estrogen and progesterone receptors was negative in one study in which that issue was investigated.³²⁶ Fibroblasts are identified on ultrastructural examination.¹³⁵⁸

Differential diagnosis

Superficial angiomyxomas can often be distinguished from aggressive angiomyxoma and angiomyofibroblastoma because of their frequent occurrence outside of the genital/perineal region, their multinodularity, the abundance of mucin and low cellularity, and the absence of a perivascular arrangement of stromal cells.¹³⁶³ In addition, the association with epithelial proliferations in up to 30% of cases is distinctive. Therefore, the histopathologic differential diagnosis for superficial angiomyxomas often includes cutaneous lesions that combine mucin deposition with epithelial proliferation, such as trichogenic myxoma, trichodiscoma, and myxoid perifollicular fibromas, and focal mucinosis.^{1358,1360}

Tumors of fat

Nevus lipomatosus	1016	Pseudolipomatosis cutis	1018	Sclerotic (fibroma-like) lipoma	1021
Piezogenic pedal papules	1017	Lipoma and lipomatosis	1018	Spindle cell lipoma	1022
Lipoblastoma	1017	Angiolipoma	1019	Pleomorphic lipoma	1023
Lipofibromatosis	1017	Adenolipoma	1021	Hibernoma	1023
Hemosiderotic fibrolipomatous tumor	1018	Chondroid lipoma	1021	Atypical subcutaneous fatty tumors	1024
		Ossifying lipoma	1021	Liposarcoma	1025

The role of subcutaneous fat and the consequences of its increase and decrease have received little attention in the dermatological literature until comparatively recently.^{1,2} There are two types of adipose tissue, white and brown, that have different roles in energy metabolism. Most tumors of fat are derived from white adipocytes, but the rare hibernoma is derived from brown adipose tissue. The lipoma is by far the most common tumor of fat.

In addition to mature adipocytes, subcutaneous and soft tissue fat contain an admixture of small blood vessels, nerve tissue, fibroblasts, and adipocyte precursor cells known as preadipocytes.² Each of these constituent cells may give rise to tumors.

Resnik and Kutzner have drawn attention to an earlier observation that may be misinterpreted by pathologists unaware of this change:³ both normal adipocytes and fat cells found in lipomas and liposarcomas may have an intranuclear vacuole, which had been called 'loch-kern' (German; *Loch* = hole and *Kern* = nucleus). Variants of this phenomenon have been described.³

The tumors of fat are a histologically diverse group. Fortunately, most have well-established diagnostic criteria and present no difficulty in diagnosis. However, there are three benign fatty tumors – spindle cell lipoma, sclerotic lipoma, and pleomorphic lipoma – that may cause diagnostic problems, sometimes leading to a mistaken diagnosis of liposarcoma.

Lipomatous tumors of different types appear to harbor CD34⁺ interstitial dendritic cells. Clonal expansion of the CD34⁺ cells may account for the development of spindle cell lipomas and the spindle cell component in some dedifferentiated liposarcomas.^{4,5}

Most tumors of fat, excluding angiolipomas, have specific aberrations of their karyotype. On this basis, it has been suggested that angiolipomas (see later) are not true lipomas but, rather, a hamartoma of blood vessels and fat.⁶

NEVUS LIPOMATOSUS

Nevus lipomatosus, also known by the complicated term 'nevus lipomatosus cutaneus superficialis (Hoffmann-Zurhelle)',^{7,8} is a rare type of connective tissue nevus characterized by the presence of mature adipose tissue in the dermis. It is found as plaques or solitary lesions or in an extremely rare generalized form.

The plaque type has aggregations of flesh-colored or yellow papules and nodules that are present at birth or that develop in the first two decades of life.⁹ There is a predilection for the pelvic girdle, particularly the gluteal region. Other sites, such as the face and scalp, are rarely involved.^{10–13} Lesions are usually unilateral and sometimes in a linear or zosteriform arrangement. The surface of most lesions is smooth, although it may be verrucous or dimpled.¹⁴ Surface comedones have been noted occasionally. Lesions usually develop insidiously but later become reasonably stable. There is one report with an associated chromosomal abnormality, a deletion of 2p24.¹⁵

The colocalization of nevus lipomatosus and lipedematous scalp (see later) has been reported.¹³

The solitary form consists of isolated papules or nodules that may appear anywhere on the body but with a predilection for the trunk.¹⁶ They may not appear until the fifth decade. They usually have a broader base than the common skin tag (acrochordon), but there are some who doubt the existence of the solitary form, preferring to regard them as skin tags or 'pedunculated lipofibromas'.^{7,17}

There are reports of more generalized body involvement with a markedly folded skin surface ('Michelin man' appearance).^{18–20} The generalized form needs to be distinguished from the abnormal fat distribution, which occurs particularly in the buttock region, in congenital disorders of glycosylation (CDG).²¹ Folds of fat hang down from the buttocks in CDG-1a (OMIM 212065).²¹

Figure 35.1 Nevus lipomatosus. Mature fat cells replace much of the dermis. Sometimes they extend to the undersurface of the epidermis. (H&E)

Histopathology^{7,22}

The basic abnormality is the presence of varying amounts of mature adipose tissue in the dermis, often not connecting with the fat of the underlying subcutis. The fat can constitute from less than 10 to 70% of the lesion. When there is only a small amount of fat, it is usually localized around the subpapillary blood vessels. Some authors have indicated a requirement for fat to be present in the papillary dermis in solitary cases to distinguish them from skin tags,²² but this feature is not always present, even in the plaque variant (**Fig. 35.1**).

There are also abnormalities in the other connective tissue components of the dermis,⁷ including some thickening of the collagen bundles.²³ In approximately half of the cases, the deeper elastic tissue is increased, although there may be a reduction in elastic fibers superficially. There is an increase in the number of fibroblasts in the papillary dermis and also of mononuclear cells, including mast cells, elsewhere in the dermis. Blood vessels are increased in the papillary dermis, and subjacent to this there may be some ectatic vessels. In one case, the vessels were so pronounced that a diagnosis of an associated angio-keratoma was made (on biopsy).²⁴ Vessels are also increased in the ectopic dermal fat. Pilosebaceous follicles are often reduced, but in one report they were hypertrophic.²⁵ The presence of folliculosebaceous cystic hamartomas and, in one case, a dermoid cyst within a giant nevus lipomatosus is difficult to explain on histogenetic grounds.^{26,27} However, reports continue to appear of nevus lipomatosus associated with dilated follicles,²⁸ a trichofolliculoma,²⁹ and a folliculosebaceous component resembling sebaceous trichofolliculoma or folliculosebaceous cystic hamartoma.³⁰

The epidermal changes are variable. There is often some undulation with acanthosis and even mild papillomatosis,³¹ and there may be mild hyperpigmentation of the basal layer. The changes may resemble those of an epidermal nevus. Dilated follicular ostia will be present, if there are comedones clinically.

Nevus lipomatosus should be distinguished from old nevocellular nevi, in which there may be large amounts of fat and sometimes only small areas of nevus cells. Focal dermal hypoplasia also has fat in the dermis, but in this condition there is extreme attenuation of collagen as well as vast clinical differences. The dermal variant of spindle cell lipoma has more spindle-shaped cells present as well as a fibromucinous stroma.

Electron microscopy

Electron microscopy has shown mature lipocytes in the perivascular region,³² and in one study, a vascular origin for the fat cells was suggested.³³

PIEZOGENIC PEDAL PAPULES

In piezogenic pedal papules, there are usually multiple small papulonodules on the heels^{34–39} that have a tendency to disappear when pressure is relieved from the heels.³⁹ Although most are painless and small,⁴⁰ there are a few reports of a painful variant.^{35–37,41} This entity has been reported in one-third of a group of patients with Ehlers–Danlos syndrome and in the Prader–Willi syndrome.^{38,42}

Piezogenic pedal papules are thought to represent pressure-induced herniations of the subcutaneous fat through acquired or inherited defects in the connective tissue of the heel.^{38,43,44}

Similar lesions (piezogenic wrist papules) have been reported on the wrist.⁴⁵ A case of piezogenic palmar papules has been reported.⁴⁶ It was due to a subcutaneous lipoma that herniated into the dermis at several points.⁴⁶

Infantile pedal papules, congenital adipose plantar nodules,⁴⁷ and congenital fibrolipomatous hamartoma^{48–51} all refer to the same entity (OMIM 609808), which differs slightly from piezogenic pedal papules. Infantile pedal papules present at birth or in infancy as painless, symmetric nodules on the medial aspect of the heel.⁵² Autosomal dominant inheritance was present in three family members from two generations.⁵³ Most cases are sporadic. In a recent study, they were found in 5.9% of newborns and 39.4% of infants.⁵⁴ They were not biopsied.

Histopathology^{36,37}

There is thickening of the dermis in the painful variant, with loss of the normal small fat compartments in the lower dermis and subcutis. These appear to coalesce as a result of degeneration of the thin fibrous septa.^{36,38,39} There may also be protrusion of these enlarged fat lobules into the dermis.³⁷ In **infantile pedal papules**, reported under several names (mentioned previously), there are well-defined lobules of mature fat in the mid and deep dermis, mostly in a periadnexal distribution.^{47,48} Mucinous deposits are often present at the periphery of the lesion and within fat lobules.⁵⁵ Similar histological findings (clusters of adipocytes around eccrine ducts) are present as a consequence of fibrous amniotic bands producing strictures of the lower legs.⁵⁶ Biopsy of a lesion designated congenital fibrolipomatous hamartoma showed lobules composed of mature adipocytes encased in collagen with increased numbers of blood vessels and normal nerve fibers.^{57,58}

LIPOBLASTOMA

Lipoblastoma is a rare, benign tumor of infants and young children, thought to be related to fetal white fat.^{59–63} It may also occur

in adolescents and young adults.⁶⁴ Most lipoblastomas occur on the proximal extremities, trunk, and head and neck.⁶⁵ Rare sites include the scrotum and vulva.^{65–68} Some earlier reports of liposarcoma in infants probably included examples of this entity.⁶⁹ Chung and Enzinger delineated a circumscribed, usually superficial type and a less common diffuse form, often in the deeper soft tissues, analogous to diffuse lipomatosis.⁶¹ In one study of 14 cases, 6 were of the circumscribed type and 8 were diffuse and ill-defined (lipoblastomatosis),⁷⁰ whereas in another study of 25 cases, 11 were circumscribed (discrete) and 14 were diffuse.⁷¹ Lipoblastoma/lipoblastomatosis behaves in a benign manner, although local recurrence sometimes occurs.⁷¹ No metastases have been reported.

Cytogenetic studies have shown that the majority of lipoblastomas have rearrangements of 8q11–13, with similar numbers showing polysomy of chromosome 8.^{64,72} A recent case was associated with a t(3;8)(p13;q21.1) translocation.⁷³ Many other abnormalities have been reported, including cases with a complex or even normal karyotype.^{65,74} The altered gene is *PLAG1*, an oncogene that encodes a zinc finger protein involved in transcriptional regulation.^{65,74} The oncogenic capability of *PLAG1* is mediated, in part, by the IGF-II mitogenic signaling pathway.⁷⁵ This gene also plays a role in other human tumors, such as hepatoblastoma and acute myeloid leukemia.⁷⁵ Rearrangement of *HMG2* instead of *PLAG1* has been reported in a recent case.⁷⁶

Lipoblastomas are light yellow to tan-yellow tumors, averaging 5 cm in greatest diameter, with focal gelatinous areas on the cut surface. Larger variants have been reported.⁶⁵ They are usually thinly encapsulated.

The treatment of choice for the localized variant is complete yet conservative surgical excision,⁶³ whereas for the diffuse variant, complete excision may not be possible. Local recurrence has been reported in up to 22% of patients, especially those with incompletely excised lesions of the lipoblastomatosis (diffuse) subtype.⁷⁷

Histopathology⁶¹

The tumor is lobulated, with thin, well-vascularized connective tissue septa. The lobules contain mature fat cells intermingled with spindle-shaped mesenchymal cells and various types of lipoblasts. These cells may be univacuolated, resembling signet-ring cells; multivacuolated; or granular, resembling hibernoma cells (**Fig. 35.2**). In contrast to liposarcoma, there are no mitoses or nuclear atypia in the lipoblasts. There is often a plexiform capillary pattern in the lobules and also patchy myxoid stroma containing mucopolysaccharides. The myxoid matrix is sometimes a predominant feature.⁶⁴ In one report, the cells stained positively for vimentin but not for CD34, smooth muscle actin, and desmin.⁶⁶ Other reports have shown that the stellate to spindled cells within the myxoid matrix are positive for S100 protein, CD10, desmin, and CD34.⁷⁸ In another recent study, 14 of 15 lipoblastomas contained spindled cells that were desmin positive but negative for smooth muscle and muscle-specific actin, h-caldesmon, and myogenin.⁷⁹

Electron microscopy

Ultrastructural examination has confirmed the presence of lipocytes, lipoblasts, and mesenchymal cells.^{65,80} The lipid vacuoles may or may not be membrane bound.⁸¹

LIPOFIBROMATOSIS

Lipofibromatosis is a rare pediatric neoplasm, with a propensity for the hands and feet, that occurs in the subcutis and deep soft tissues.⁸² It may be present at birth. Similar cases have been diagnosed in the past as infantile fibromatosis, fibrous hamartoma of infancy, and fibrosing lipoblastoma. Regrowth or persistence of the tumor is common following incomplete excision.⁸²

Figure 35.2 Lipoblastoma. (A) The tumor is composed of mature fat cells, spindle-shaped mesenchymal cells, and a few cells with granular cytoplasm. (B) A higher power view of the same lesion. (H&E)

Histopathology

There is abundant adipose tissue, typically comprising more than 50% of the specimen, dissected by thickened septa containing a spindled fibroblastic element.^{82,83} These cells sometimes show a fascicular growth pattern and limited mitotic activity. Small collections of univacuolated cells are often present at the interface between the fat and the fibroblastic element. Rare pigmented cells have been described.⁸²

HEMOSIDEROTIC FIBROLIPOMATOUS TUMOR

This tumor, reported by Browne and Fletcher in 2006 (with British English spelling of two of the words in the title),⁸⁴ is the same entity as a hemosiderotic fibrohistiocytic lipomatous lesion reported a few years earlier.⁸⁵ Although originally regarded as reactive in nature (sometimes to trauma), it is now thought to be neoplastic because of its infiltrative border and local recurrence in some cases. No metastasis has been reported.⁸⁴

Most cases have been reported in the ankle/foot region, but unlike lipofibromatosis, there is a predilection for middle-aged and elderly individuals.⁸⁴ Lesions range in size from 1 to 13 cm. They are situated in the superficial soft tissues/subcutis. Grossly, the lesions are fatty/gelatinous or lipoma-like.

Although Folpe and Weiss have regarded this lesion as a precursor of pleomorphic hyalinizing angiectatic tumor,⁸⁶ this concept is not supported by Browne and Fletcher.⁸⁴ A hybrid myxoinflammatory fibroblastic sarcoma and hemosiderotic fibrolipomatous tumor has been reported, showing a der(10)t(1;10) and abnormalities of chromosome 3 – anomalies that have been reported in both entities ('der' is a cytogenetic designation for 'derivative chromosome', resulting from a rearrangement that involves two or more chromosomes or multiple aberrations in a single chromosome).⁸⁷ Another study found a t(1;10) translocation in both lesions, with resulting fusion of the *TGFBR3* gene at 1p22 with *MGEA5* on 10q24; this information, together with the synchronous or metachronous occurrence of both lesions, is further evidence for a relationship between myxoinflammatory fibroblastic sarcoma, and hemosiderotic fibrolipomatous tumor.⁸⁸ Further support is provided by a genetically confirmed case of hemosiderotic fibrolipomatous tumor that underwent sarcomatous transformation and metastasis.⁸⁹

Histopathology

This tumor has varying proportions of mature adipocytes and fibroblastic spindle cells, associated with usually abundant deposits of hemosiderin, found predominantly in macrophages within the spindle cell component.⁸⁴ The adipocytic component has a partly lobular configuration that is traversed by spindle cell septa of variable size.⁹⁰ Often, the spindle cells form nodules within the fat. The spindle cells are arranged in fascicles, and there may be focal myxoid change in this component. Sometimes the spindle cells infiltrate the fat in a honeycomb pattern, reminiscent of dermatofibrosarcoma protuberans.⁸⁴

Inflammatory cells are scattered through each lesion. They are mainly lymphocytes and plasma cells with a few mast cells and eosinophils. Osteoclastic giant cells are often present. The hemosiderin is largely confined to the cellular fibrous septa and spindle cell nodules.

Of the 9 cases tested in the series reported by Browne and Fletcher, 7 showed strong positivity for CD34 in the spindle cell component. In all 10 cases examined, the spindle cells were negative for SMA, desmin, CD68, and S100 protein.⁸⁴

PSEUDOLIPOMATOSIS CUTIS

The term 'pseudolipomatosis cutis' was coined by Trotter and Crawford for the incidental finding of grouped and coalescent spaces in the dermis resembling fatty infiltration.⁹¹ Similar changes have been reported in acrodermatitis chronica atrophicans (see p. 681) and in a case of psoriasis (see p. 88).⁹² Although Trotter and Crawford regarded these spaces as artifactual, subsequent correspondence refuted this suggestion in favor of a prelymphatic origin.⁹²

LIPOMA AND LIPOMATOSIS

Lipomas are relatively common, usually asymptomatic, subcutaneous tumors with a predilection for the upper trunk, upper extremities, thighs, and neck of individuals in the fifth and sixth decades.⁹³ Lesions on the finger are very rare.⁹⁴⁻⁹⁶ A deep variant arising on the forehead has been described.⁹⁷ Intramuscular lipomas may occur at other sites.⁹⁸ Lipomas account for 90% or more of tumors of fat seen in most laboratories. They are soft, often mobile, encapsulated tumors of varying size but averaging 3–5 cm in diameter. 'Giant' variants have been recorded.⁹⁹ Blunt trauma has been suggested as an etiological factor in some cases, but pseudolipomas from prolapse of fat may be difficult to distinguish from true lipomas in these circumstances.^{100,101} Multiple lipomas have developed after total body electron beam therapy.¹⁰² Ectopic axillary breast tissue may mimic a lipoma.¹⁰³

There are several distinct clinical syndromes in which disfiguring masses of mature adipose tissue develop in the subcutaneous tissues.

They are discussed in detail by Allen.¹⁰⁴ In **benign symmetric lipomatosis** (multiple symmetric lipomatosis/Madelung's disease/Launois-Bensaude syndrome; OMIM 151800), the tumors develop on the neck, back, and upper trunk, with a predilection for middle-aged men.^{105–111} Variants involving the hands,¹¹² the thighs,¹¹³ or the feet¹¹⁴ have been reported. The distinction between obesity and localized (zonal) variants of the buttocks and thighs is often problematic in females.¹¹⁵ Familial cases have also been recorded, but no pattern of inheritance has been delineated. Some cases have been associated with the mitochondrial DNA syndromes.¹¹⁶ Various metabolic abnormalities may occur in this condition,^{117,118} and there is sometimes alcohol-related liver disease, suggesting that alcoholism may be a trigger.^{115,119–122} A case with lipoatrophy of the face, mimicking highly active antiretroviral therapy (HAART)-related lipodystrophy (see later), has been reported.¹²³ In **familial multiple lipomatosis**,^{119,124–126} multiple discrete, usually asymptomatic, lipomas develop on the forearms, trunk, and thighs in the third decade. Nonsymmetrical lesions may be present.¹²⁷ An autosomal dominant inheritance has been proposed, despite the predominance in males. The gene map locus is 12q14.3. Reciprocal translocations have been reported in the lipomas that develop in familial multiple lipomatosis (OMIM 151900). The masses are encapsulated and vary from a few millimeters to 5 cm or more in diameter. In **adiposis dolorosa (Dercum's disease; OMIM 103200)**, there are painful, circumscribed or diffuse fatty deposits with a predilection for the lower legs, abdomen, and buttocks.^{128,129} There may be obesity, weakness, and mental disturbances. Familial cases related to an autosomal dominant gene with variable expressivity have been reported.^{130,131} Juxta-articular fatty deposits, resembling those seen in adiposis dolorosa, have been reported in a patient receiving long-term treatment with high doses of corticosteroids.¹³² **Diffuse lipomatosis**^{69,133–135} consists of infiltrating masses of mature adipose tissue, extensively involving part of a limb or the trunk, with onset before 2 years of age. It has been associated with tuberous sclerosis.¹³³ In **encephalocraniocutaneous lipomatosis**,^{136–139} there are subcutaneous lipomas on the scalp with overlying alopecia, as well as cranial and ocular abnormalities. The cutaneous component has been called 'nevus psiloliparus'.^{140–142} **Infiltrating lipoma of the face**¹⁴³ is another variant of this hamartomatous condition. The term has also been used for intermuscular and intramuscular lipomas.¹⁴⁴ Other variants of infiltrating lipoma occur.¹⁴⁵ **Lipedematous scalp** refers to a thickening of the subcutaneous fat of the scalp, leading to a clinically thickened and soft scalp.^{146,147} It may present as an alopecia (see p. 496). However, the precise reason for subcutaneous thickening is still the subject of debate, and subcutaneous edema may be the mechanism rather than formation of lipomatous tissue – analogous to the situation in lipedema of the lower extremities.¹⁴⁸

The use of protease inhibitors in the treatment of HIV-1 may be associated with several abnormalities of fat, including subcutaneous lipomas,¹⁴⁹ angioliipomas,¹⁵⁰ peripheral lipodystrophy (see p. 545), and benign symmetrical lipomatosis.¹⁴⁹ Multiple lipomas have developed in a patient undergoing HAART that did not include a protease inhibitor.¹⁵¹

Nearly half of all lipomas have an abnormal karyotype, characterized by rearrangements of three different chromosome regions: 12q14–q15, 6p21, and 13q12–q14. Translocations involving the long arm of chromosome 12 and chromosome 3 (band q27–28) are a common finding, but other chromosome bands may be involved in the translocation.¹⁵² At the molecular level, 12q14–q15 rearrangements affect the high-mobility-group (HMG) protein gene *HMGIC*. Other mesenchymal tumors share abnormalities of this or related genes.¹⁵²

Although surgical extirpation is the usual method of treatment, liposuction and the injections of phosphatidylcholine have also been used.^{153–155} Dramatic reduction in the size of a lipoma occurred in a patient commenced on statin therapy.¹⁵⁶ In adiposis dolorosa (Dercum's disease), intravenous lidocaine and low-dose, daily prednisolone have helped in some cases. Improvement has been reported

Figure 35.3 Lipoma. There are sheets of mature fat, dissected by thin, incomplete fibrous septa containing blood vessels. (H&E)

with the combined use of infliximab and methotrexate.¹⁵⁷ Surgical debulking produced an acceptable cosmetic result in a patient with lipedematous alopecia.¹⁵⁸

Histopathology

Lipomas are composed of sheets of mature fat dissected by thin, incomplete fibrous septa containing a few blood vessels (Fig. 35.3). A fibrous capsule is present. Variants with increased stromal fibrous tissue (*fibrolipomas*) are found. In neural *fibrolipoma* (*fibrolipomatous hamartoma of nerve*, *neural lipofibromatous hamartoma*¹⁵⁹), fibrofatty tissue surrounds and infiltrates a nerve and/or its small branches (Fig. 35.4).^{160,161} If blood vessels constitute more than 5% of the mass, the lesion is best regarded as an *angioliipoma* (see later). Eccrine sweat ducts are rarely present. Such variants have been termed *adenoliipomas* (see later). The admixture of smooth muscle and fat constitutes a *myoliipoma*. Rarely, the lipomatous component is mildly atypical.¹⁶² A unique case with myxoid change and synovial metaplasia has been reported.¹⁶³ Membranous fat necrosis is another rare secondary change.¹⁶⁴ Abundant fat may be present in some mixed tumors of the skin (chondroid syringoma).¹⁶⁵ Other unusual variants, usually seen in soft tissues, are the lipoma with osteocartilaginous metaplasia¹⁶⁶ and the chondroid lipoma.¹⁶⁷

The changes produced by treatment with phosphatidylcholine injections (discussed previously) are similar to factitial panniculitis. In the first few days, there is a lobular neutrophilic infiltrate with partially destroyed fat cells. Lymphocytes are present 10 days after treatment, and by 2 months there are lipophages and septal fibrosis.¹⁵⁴ Granulomas and pseudomembranous change have also been seen.¹⁵⁵

The histological appearances of the various lipomatosis syndromes are similar, except for the absence of a capsule and increased fibrous tissue in multiple symmetrical lipomatosis and also the 'infiltrative' properties of the fat in diffuse lipomatosis. Granulomatous panniculitis has been found in a painful mass in Dercum's disease, although most reports have shown normal fat.¹²⁸

Massive localized lymphedema associated with morbid obesity is usually easy to pick from a lipoma variant even on a small biopsy.¹⁶⁸ There is marked dermal edema, no adipocytes, and a mild perivascular infiltrate of lymphocytes.¹⁶⁸

ANGIOLIPOMA

Angioliipomas are subcutaneous tumors of the extremities and trunk; they comprise approximately 10% of tumors of fat.^{169–171} They are often

Figure 35.4 (A) Neural fibrolipoma (fibrolipomatous hamartoma of nerve). (B) Mature fat surrounds and to a lesser extent infiltrates a nerve. (H&E)

Figure 35.5 Angiolipoma. Mature fat cells are admixed with small blood vessels. (H&E)

multiple, with the first tumors appearing just after puberty.^{169,172} A family history is found in approximately 10% of cases (OMIM 206550), but no pattern of inheritance has been proposed. A history of previous trauma to the site or the therapeutic use of protease inhibitors is rarely elicited.^{150,173} Numerous angiolipomas appeared in a young adult male with familial angiolipomatosis upon starting anabolic steroids.¹⁷⁴ Mild pain or discomfort is often noted when pressure is applied or the lesions are moved;¹⁷⁵ the pain appears to be related to the vascularity of the lesions.

Subcutaneous angiolipomas have a normal karyotype, setting them apart from most other tumors of fat, including lipomas.¹⁷⁶ For this reason, they have been regarded as a hamartoma of blood vessels and fat rather than a true tumor of fat.⁶

Macroscopically, they are yellow, firm, circumscribed tumors, from 1 to 4 cm in diameter. They may have a yellow-red appearance on the cut surface, reflecting the degree of vascularity.

Subcutaneous angiolipomas must be distinguished from the infiltrating angiolipoma, which is a solitary lesion of the deep soft tissues.^{177,178} It is not discussed further.

Histopathology^{169,170,179}

Angiolipomas have a thin fibrous capsule with incomplete fibrous septa extending into the lesion, dividing it into lobules of different size. They are composed of variable proportions of fatty tissue and blood vessels (Fig. 35.5). The fat cells are mature, with a single vacuole and an eccentric nucleus. The vascular component, which comprises 5–50% or more of the tumor, consists of groups of capillaries and occasional vessels of larger caliber.¹⁷⁹ Only sparse fat cells were present in the lesion reported as a *cellular angiolipoma*,¹⁸⁰ which was composed almost entirely of small vessels and scattered short spindled cells between vascular channels.¹⁸¹ In the usual type of angiolipoma, there are prominent pericytes around the vessels.¹⁷⁰ Erythrocytes are present within the lumen, and scattered fibrin thrombi are easily found. In one report, hemorrhagic infarction of the fat was present in association with numerous fibrin thrombi and disseminated intravascular coagulation.¹⁸²

Several cases with a myxoid stroma have been reported (**angio-myxolipoma**).^{183–185} In one case, the cells in the myxoid area expressed CD34.¹⁸⁵ This entity is probably a variant of what has been called

dendritic fibromyxolipoma (see p. 1022). This tumor shares cytogenetic changes with lipoma, spindle cell/pleomorphic lipoma, and myxoma, setting it apart from the angiolipoma, which has a normal karyotype.¹⁸⁶

There are numerous mast cells throughout the tumor.¹⁸⁷ Bodian stains for small nerves have been consistently negative, but large myelinated nerves have been found in the surrounding connective tissue.¹⁷⁹ Approximately one-third of cases express androgen receptors.¹⁷⁴ The short-spindled cells in cellular angiolipoma are vimentin positive and variably stain for the endothelial markers CD31 and CD34.¹⁸¹

The finding of a cutaneous melanoma that metastasized to an angiolipoma appears to have been a fortuitous event.¹⁸⁸

Electron microscopy

Ultrastructural examination has shown mature fat cells interspersed with blood vessels lined by one or more endothelial cells.¹⁷⁰ Interestingly, Weibel–Palade bodies, characteristic of endothelial cells, were exceedingly sparse in the endothelium.¹⁷⁰ The significance of this finding is uncertain.

ADENOLIPOMA

This rare microscopic variant of lipoma, characterized by mature fat admixed with eccrine glands, was first reported in 1993.¹⁸⁹ It is probably an analogue of adenolipomas reported in other organs.¹⁹⁰ The cutaneous variant occurs in the dermis or subcutis, with a predilection for the thigh.¹⁹⁰ The lip was involved in one case.¹⁹¹

On gross examination, they have a soft, yellow, lobulated appearance, often surrounded by a thin capsule.¹⁹⁰

Histopathology

Adenolipoma is characterized by lobules of mature adipose tissue admixed with normal-appearing eccrine glands in varying proportions. Some entrapped eccrine glands show cystic change. A case has been reported in which there was a cystic apocrine component admixed with fat.¹⁹⁰ The authors acknowledged that this tumor, which they called ‘**apocrine cystic adenolipoma**’, could represent entrapment of epithelial structures within a lipoma. A hyperplastic apocrine gland component was also present in a fatty tumor called ‘**cutaneous myxolipoma with glandular differentiation**’.¹⁹² Interestingly, a 6p21 chromosomal rearrangement was present.¹⁹² Several recent reports have described complex lesions composed of not only adipose tissue and eccrine or apocrine glands but also spindle cell elements (in some cases, CD34⁺), inflammatory cells, and, in one case, fibrous and vascular tissue as well as an extensive glandular component.^{193,194}

CHONDROID LIPOMA

The chondroid variant of lipogenic tumor was described by Meis and Enzinger in 1993.¹⁹⁵ The lesion is usually deep seated, although subcutaneous variants occur. It has a predilection for females. The lower extremity is the most common location. Its histogenesis is disputed. One view is that the lesion is composed only of white adipocytes, but the other view suggests that the cells have features of embryonal fat and, to a lesser extent, embryonal cartilage.¹⁹⁶ A cytogenetic study has shown a three-way translocation between chromosomes 1, 2, and 5 together with an 11;16 translocation with a breakpoint in 11q13.¹⁹⁷ This results in a fusion oncogene, *C11orf95–MKL2*, that is characteristic for chondroid lipoma.¹⁶⁷

Chondroid lipomas are firm yellow tumors averaging 3–5 cm in diameter.

Histopathology

The tumors are lobulated, with a thin capsule.^{195,196,198} There are multivacuolated tumor cells with nuclear indentation, resembling lipoblasts, within a chondromyxoid matrix. In addition, there are clusters of mature adipocytes with a single vacuole that occupies most of the cytoplasm. The cells contain glycogen and fat. The stroma is strongly metachromatic with toluidine blue at pH 4.0. Inflammation calcification and/or metaplastic bone formation can occur.¹⁶⁷ An osteochondrolipoma variant has also been reported.¹⁹⁹

Immunoperoxidase methods demonstrate vimentin and S100 protein in the tumor cells (lipoblasts)^{196–198} and CD68 in vacuolated cells. Occasional cytokeratin staining, collagen IV staining of the stromal fibrillar network, and cyclin D1 and PCNA positivity are seen in some cases.¹⁶⁷

Electron microscopy¹⁹⁸

The tumor cells have numerous lipid vacuoles of varying size in the cytoplasm. There are glycogen granules, mitochondria, and pinocytotic vesicles. The cells are set in a flocculent stroma, with cartilage demonstrable in some areas.¹⁹⁶

Differential diagnosis

The differential diagnosis includes spindle cell lipoma (lack of chondroid features; diffusely CD34⁺), well-differentiated liposarcoma (sheets of adipocytes with fibrous septa; rare lipoblasts; nuclear atypia), myxoid liposarcoma (uniform cells with small, ovoid nuclei; delicate branching capillaries), myxoid chondrosarcoma (multilobulated; chondroblasts; absent vacuoles or fatty component), and myoepithelial tumors (lack of lipoblast-like cells; cells that express cytokeratin, calponin, and epithelial membrane antigen).¹⁶⁷ Characteristic cytogenetic features are found for each of these tumors.^{152,200–202}

OSSIFYING LIPOMA

Ossification is another change that can be seen in lipomas. Only 25 cases of this rare phenomenon had been reported by late 2007.²⁰³ They arise in the subcutaneous and deeper fat of the trunk, the extremities, or the head and neck region.²⁰³ No recurrences have been recorded. Ossification may be secondary to the long duration of the underlying lipoma.

Histopathology

The adipose tissue component is usually predominant.²⁰³ The mature bone, which is usually surrounded by fibrous tissue bands, is irregular in distribution. Chondroid structures are seen in nearly half of the cases.²⁰³

SCLEROTIC (FIBROMA-LIKE) LIPOMA

Sclerotic lipoma, first described by Zelger and colleagues in 1997, is a further rare variant of lipoma.²⁰⁴ It shows prominent stromal sclerosis. It is more common in males. There is a predilection for the distal extremities, particularly the fingers.^{204,205} The scalp has also been involved.²⁰⁶ Excision is usually curative.²⁰⁵

Histopathology

Sclerotic fibromas are circumscribed nodules in the subcutis with a prominent sclerotic stroma, sometimes in a storiform arrangement. The spindle and stellate-shaped cells are cytologically bland with rare, if any, mitoses.²⁰⁵ There is a resemblance to fibrolipoma or sclerotic fibroma (circumscribed storiform collagenoma), depending on the

amount of admixed fat. The number of adipocytes varies from case to case and in different parts of the same tumor. Small foci containing numerous spindle-shaped to stellate cells may be found. The *fibrous spindle cell lipoma* has abundant fibrous stroma; sclerosis is not a feature.²⁰⁷

Immunohistochemistry shows staining for vimentin and also for S100 protein at the margins of the adipocytes.²⁰⁴ In a large series of 21 cases, the nonlipogenic tumor cells were immunoreactive for CD99 (6 of 6 cases), CD34 (6 of 8 cases), S100 protein (4 of 7 cases), and smooth muscle actin (2 of 6 cases).²⁰⁵

SPINDLE CELL LIPOMA

Spindle cell lipoma is a slow-growing benign tumor of the subcutis. It primarily affects the shoulders, upper back, and back of the neck of men in the fifth to seventh decades.^{208,209} Fewer than 10% of cases occur in women.²¹⁰ Uncommonly, the tumors arise on the extremities,²⁰⁸ lower trunk,²¹¹ oral cavity,²¹⁰ and the head.^{212,213} They are generally painless. Multiple lesions are rare; the clinical presentation of such cases may mimic symmetrical lipomatosis (discussed previously).²¹⁴ Some cases are familial.²¹⁴ Cytogenetic studies generally show monosomy 16 or partial loss of 16q – a finding distinct from liposarcoma.⁶ Anomalies of chromosome 13 have also been reported.²¹⁵ There is a view that spindle cell lipoma and pleomorphic lipoma form a spectrum of adipose tumors; this is supported by the finding of similar cytogenetic abnormalities.^{216,217}

Macroscopically, the tumors are soft, oval, lobular masses with an average diameter of 5 cm. They are yellow or gray-yellow in color, and they sometimes have a glistening or mucoid appearance on the cut surface.

Histopathology^{208,211,218}

Spindle cell lipomas are usually circumscribed unencapsulated tumors of the subcutis, although occasionally they are poorly delimited and extend into the dermis or underlying tissues. A variant confined to the dermis (dermal spindle cell lipoma) has been reported.^{217,219,220} They are composed of a variable mixture of spindle cells and adipose tissue (Fig. 35.6). Sometimes the proliferation of spindle cells is localized. The spindle cells are usually small and elongated and arranged haphazardly. Occasionally, they may show a palisaded or fascicular pattern in some areas. A few spindle cells may show small cytoplasmic vacuoles. There is no increase in mitoses, although there may be some nuclear variability. The spindle cells are separated by variable amounts of collagen. Sometimes this stroma shows focal myxomatous change, which stains positively for acid mucopolysaccharides. The tumor reported as *dendritic fibromyxolipoma* is probably the same adipocytic lesion as that reported as vascular myxolipoma (angiomyxolipoma).^{90,183} In many ways, this tumor resembles a spindle cell lipoma with stromal myxoid areas.

The intervening fat cells are mature and univacuolated, resembling normal fat. No lipoblasts are present. In approximately 10% of consultation cases, fat constitutes less than 5% of the tumor. Such cases can pose diagnostic difficulties because of the dearth of fat.²²¹ The terms ‘low-fat’ and ‘fat-free’ spindle cell lipoma have been proposed for these variants.²²¹ A few tumors have a prominent vascular pattern,²²² and this may resemble a lymphangioma or hemangiopericytoma in some areas.²⁰⁸ The **lipomatous hemangiopericytoma** is a deep-seated tumor and is not considered further.⁹⁰ At other times, there are irregular and branching spaces with villiform connective tissue projections, giving a striking angiomatoid appearance.^{90,223,224} This is the so-called ‘*pseudoangiomatous variant*’ (Fig. 35.7). A few inflammatory cells may be found in the walls of these vessels. Mast cells are usually present throughout the stroma. Extramedullary hematopoiesis has been

Figure 35.6 (A) Spindle cell lipoma. (B) The tumor is composed of fat cells, fibrous tissue, and scattered spindle-shaped cells. (H&E)

Figure 35.7 Spindle cell lipoma. This is the pseudoangiomatous variant with vascular-like spaces of irregular shape. (H&E)

reported in one case.²²⁵ The cytoplasm of the spindle cells stains for vimentin²⁰⁹ and CD34.^{5,226,227} Some factor XIIIa⁺ stromal cells are also present.⁴ In one series, all 22 cases expressed androgen receptors, whereas in conventional lipomas, 70% were positive, but the staining was often weak.²²⁸

Electron microscopy

Ultrastructurally, the spindle cells resemble fibroblasts. A few contain cytoplasmic lipid droplets.^{208,209}

Differential diagnosis

Solitary fibrous tumor can resemble spindle cell lipoma, and both tumors possess CD34⁺ spindle cells. However, spindle cell lipoma differs clinically in its frequent occurrence on the posterior neck or shoulder of middle-aged to elderly men, and it differs microscopically by the presence of interspersed mature lipocytes and numerous mast cells. Mammary-type myofibroblastoma very closely resembles spindle cell lipoma morphologically, but it differs in that, although CD34⁺, it also demonstrates immunoreactivity for desmin and muscle-specific actin. Fibrous hamartoma of infancy has some features in common with spindle cell lipoma but arises in an entirely different patient population and lacks CD34 positivity. In the past, spindle cell lipoma was sometimes confused histologically with liposarcoma and other spindle cell sarcomas. The absence of multivacuolated lipoblasts and lack of significant nuclear atypia exclude liposarcoma. Other findings that contribute to a diagnosis of well-differentiated liposarcoma include a high Ki-67 proliferation index and positive immunoreactivity for Mdm2.²²⁹

PLEOMORPHIC LIPOMA

Pleomorphic (giant-cell) lipoma is a benign tumor of adipose tissue with atypical histological features that may lead to a misdiagnosis of liposarcoma.^{230,231} It presents as a soft subcutaneous mass, averaging 5 cm in diameter. A case confined to the dermis has been reported.²³² Pleomorphic lipoma has a predilection for the shoulders, back of the neck, back,^{230,233} and, less frequently, the face and thighs²³⁴ of middle-aged to elderly males.²³⁰ Pleomorphic lipomas resemble spindle cell lipomas cytogenetically with a consistent loss of chromosome 16q material.⁶ For this reason, these two entities are often regarded as forming a spectrum of related adipose tumors.²¹⁷ Macroscopically, the tumor resembles a lipoma, although gelatinous gray areas may be present on the cut surface. Some of the reported cases of atypical lipoma are examples of this entity.^{235,236}

Histopathology^{230,234}

These circumscribed tumors have an intricate mixture of mature adipose tissue, collagen, and myxoid areas interspersed with cellular foci of varying amounts. In addition to lipoblast-like cells, the tumor includes spindle and giant cells, with the latter being both uninucleate and multinucleate in type (Fig. 35.8). There are variable numbers of giant cells with marginally placed and often overlapping nuclei – the so-called ‘florete giant cells’ (Fig. 35.9). Sometimes the nuclei of some giant cells are smudgy, with indistinct chromatin. Mitoses are rare. Focal collections of lymphocytes and plasma cells are often found within the tumor. A variant with pseudopapillary structures resembling those seen in pseudoangiomaticous spindle cell lipoma (discussed previously) has been described.²³⁷

At times, the pleomorphic lipoma is a circumscribed nodule within an otherwise typical lipoma. Areas resembling spindle cell lipoma may sometimes be present within pleomorphic lipomas. As in spindle cell lipoma, there are CD34⁺ and factor XIIIa⁺ stromal cells.⁴ A ‘fat-free’ pleomorphic lipoma has also been described.²³⁸

Differential diagnosis

Pleomorphic lipoma may be distinguished from liposarcoma by the florete giant cells, the pyknotic or smudgy nuclear features, and the absence of mitoses.²³⁹

Figure 35.8 (A) Pleomorphic lipoma. (B) Some fat cells have hyperchromatic nuclei with a smudgy appearance. There are no mitoses. **(C)** Another case showing many hyperchromatic and bizarre nuclei. (H&E)

HIBERNOMA

Hibernoma is a rare benign tumor of the subcutaneous²⁴⁰ and deeper soft tissues,²⁴¹ generally considered to arise from brown fat. It is found in the scapular area, axilla,²⁴² lower neck,²⁴⁰ and, less commonly, in the thigh,^{243,244} abdominal wall,²⁴⁵ and retroperitoneum.²⁴⁶ It grows slowly.

Figure 35.9 Pleomorphic lipoma. Floret giant cells have marginally placed, overlapping nuclei. Some nuclei have smudged, indistinct chromatin. (H&E)

There may be increased warmth over the area.²⁴⁷ Cytogenetic studies have shown rearrangements in the 11q13 region, frequently including deletions in the region between *PLCB3* and *PPP1A*, leading to loss of the *MEN1* gene.^{197,248} In addition, abnormalities involving chromosome 10q22 have been reported.⁶ Loss of two tumor suppressor genes located 3 Mb apart, *AIP* and *MEN1*, is apparently essential for the development of hibernomas.²⁴⁹

Grossly, hibernomas are tan-brown lobulated tumors, averaging 10 cm in diameter. Several possible malignant variants have been reported, but these have been disputed by others.^{240,250}

Histopathology^{240,245}

The tumors are thinly encapsulated and divided into lobules by thin septa. There are usually prominent blood vessels in the septa and lobules; in one case with possible endocrine activity,²⁴³ they assumed a prominent sinusoidal pattern.

There are three cell types with transitional forms:²⁴⁶ large, coarsely vacuolated cells with multiple vacuoles; univacuolated cells; and smaller cells with granular cytoplasm (Fig. 35.10). Vacuoles stain with oil red O in frozen sections. Lipofuscin pigment is also present.²⁵¹ There is often a prominent nucleolus, but there are no mitoses. Furlong *et al.* described three microscopic variants of hibernoma: lipoma-like, spindle cell, and myxoid.²⁵² Lipoma-like variants feature mainly univacuolated adipocytes ('white fat' cells) and scattered, granular or pale hibernoma cells (Fig. 35.11).²⁵³ The spindle cell type is quite uncommon, representing 2% of all hibernomas.²⁵⁴ In addition to the typical multi-vacuolated component, there are areas of spindle cells that lack vacuolization and are CD34⁺.²⁵⁴

Fine needle aspiration cytology is an effective method for diagnosis of hibernoma.²⁵⁵

Electron microscopy

Electron microscopy shows abundant lipid droplets, numerous pleomorphic mitochondria with transverse cristae, and a well-formed basal lamina.^{245,246,251,256}

Differential diagnosis

The distinctive microscopic characteristics of brown fat usually ensure ready recognition of hibernoma. The diagnosis could potentially be missed in examples of lipoma-like or spindle cell variants. Lipoblastomas containing multivacuolated or granular cells could be confused with hibernoma, and the myxoid component of the former

Figure 35.10 (A) Hibernoma. (B) Some cells are coarsely vacuolated, whereas others have a 'granular' cytoplasm. **(C)** A high-power view of the cells. (H&E)

tumor could further create a resemblance to the myxoid variant of hibernoma.

ATYPICAL SUBCUTANEOUS FATTY TUMORS

This category of fatty tumors is not a distinct entity but, rather, the name given by Allen and colleagues to borderline lesions seen in a

Figure 35.11 Lipoma-like hibernoma. The tumor consists mainly of univacuolated adipocytes, but there are scattered foci of granular hibernoma cells. (H&E)

consultation practice.²⁵⁷ The term ‘atypical lipomatous tumor’ is also used.²⁵⁸ It comprises a histological spectrum ranging from atypical fibrolipomas, through various mixed spindle cell and pleomorphic lipoma patterns, to tumors indistinguishable from dedifferentiated liposarcomas.^{257,259} Of interest is the extremely good prognosis of atypical lesions confined to the subcutaneous fat, despite sometimes alarming histological features, including the presence of lipoblasts.²⁵⁷ Local recurrence can occur.

The use of cytogenetics has allowed better, and often specific, characterization of tumors in this group.²⁶⁰

LIPOSARCOMA

Liposarcoma is the most common soft tissue tumor, accounting for 16–18% of all malignant soft tissue sarcomas.²⁶¹ Only rarely do they arise in the subcutis or dermis, although they may eventually extend into it from below.^{262–264} Accordingly, they are considered only briefly. They have a predilection for the thighs and buttocks, but they may sometimes involve the head and neck^{265,266} or upper extremities. They arise in older adults and are exceedingly rare in children.^{69,267} Although a few cases have developed in patients with multiple lipomas, liposarcomas are not thought to arise from pre-existing lipomas.^{262,268} They are often large and non-encapsulated, varying in color from yellow to gray to gray-white. There may be some firmer areas and gelatinous foci in the generally soft tissue.

In 1998, primary liposarcoma of the skin (dermis) was described.²⁶⁹ Four of the seven cases arose on the scalp. The median age of the patients was 72 years. Local recurrence occurred in two patients, but no metastases or disease-related deaths were recorded.²⁶⁹ Since that time, a purely intradermal pleomorphic liposarcoma has been reported on the nose of an elderly female,²⁷⁰ and Fletcher and colleagues have reviewed a series of 57 cases of pleomorphic liposarcoma, 16 of which were superficial (dermal or subcutaneous).²⁷¹ Only two of these superficial lesions metastasized.²⁷¹

Cytogenetic studies have shown clonal karyotypic abnormalities, which often correlate with the histological subtype.²⁷² For example, the myxoid liposarcoma often demonstrates a reciprocal translocation t(12;16)(q13;p11) that fuses the *DDIT3* (*CHOP*) gene with *FUS*.^{272–278} An *EWSR1-DDIT3* fusion transcript has rarely been described in myxoid liposarcoma.²⁷⁸ A similar chromosomal abnormality has been

Figure 35.12 Well-differentiated liposarcoma. This tumor is typified by amplification of the *MDM2* gene, as shown in this fluorescence *in situ* hybridization preparation. (Image courtesy of Mark R. Wick, M.D.)

found in the round cell liposarcoma, suggesting that this variant is a poorly differentiated form of myxoid liposarcoma.^{279,280} The well-differentiated liposarcoma (including sclerosing, inflammatory, and dedifferentiated variants) is characterized by ring or long marker chromosomes derived from chromosome 12.^{277,281} These long and/or ring chromosome markers are composed of 12q13–q15 amplicons with a constant amplification of the *MDM2* gene and frequently *CDK4*.^{282–285} Immunohistochemistry can be used to detect these markers, allowing differentiation from lipomas and, in the case of the dedifferentiated variants, from other pleomorphic sarcomas (see later).^{260,282,286} The pleomorphic liposarcoma has complex karyotypes.²⁸⁷

Histopathology^{263,288,289}

There are four histological variants, although mixed forms occur.²⁹⁰

The **well-differentiated (lipoma-like) liposarcoma** (atypical lipomatous tumor) resembles normal fat.^{291,292} It accounts for 40–45% of all liposarcomas.²⁸¹ There is some nuclear pleomorphism and hyperchromatism and scattered multivacuolated lipoblasts. The diagnosis is often made in retrospect, after the first recurrence. A sclerosing variant with abundant fibrous tissue is also recognized.²⁹³ The spindle cell liposarcoma is a further variant: a relatively bland spindle cell proliferation is arranged in fascicles and whorls and set in a variably myxoid stroma.^{294,295} An epidermal inclusion cyst has been reported in a cutaneous lesion.²⁶¹ Numerous lymphocytes are sometimes present, but this feature is usually associated with the pleomorphic variant (see later).^{296,297} Fluorescence *in situ* hybridization (FISH) technology demonstrates amplification of the *MDM2* gene and/or the cyclin-dependent kinase-4 (*CDK4*) gene (Fig. 35.12). Well-differentiated liposarcomas have a good prognosis; they have a resemblance to atypical/pleomorphic lipomas, and some believe that the two tumors represent parts of a continuum rather than distinct clinicopathologic entities.

The **myxoid liposarcoma** (Fig. 35.13) consists of fusiform or stellate cells, with abundant mucoid stroma, a delicate plexiform network of small capillaries, and a variable number of signet-ring cell and multivacuolated lipoblasts.²⁶⁷ Tumor cells stain for vimentin and S100 protein. There is often focal expression of desmin and smooth

Figure 35.13 Myxoid liposarcoma. Sparse spindle-shaped cells are present in a myxoid stroma. (H&E)

muscle actin.²⁷² This variant often metastasizes to extrapulmonary sites.²⁹⁸

The **round cell liposarcoma**, which is a poorly differentiated form of myxoid liposarcoma,^{299,300} in which round cells constitute greater than 5% of the tumor, has diffuse sheets of closely arranged round or oval cells, frequently with a single small cytoplasmic vacuole.²⁸⁰ Lipoblasts are present but may be difficult to find. Mitoses are abundant in some areas. Fibrosarcoma-like areas are sometimes present. Myxoid liposarcomas may be difficult to distinguish from other cutaneous myxoid tumors or, in the case of round cell liposarcoma, from 'small round, blue cell tumors'. FISH analysis can be helpful in this regard because, as mentioned previously, myxoid liposarcoma has the characteristic t(12;16) translocation that fuses the *FUS* and *DDIT3* genes.³⁰¹

The **pleomorphic liposarcoma** (Fig. 35.14), constituting approximately 5% of liposarcomas, is a highly cellular tumor with numerous mitoses and some bizarre and extremely pleomorphic, univacuolated, and multivacuolated lipoblasts with one or more hyperchromatic nuclei.³⁰²⁻³⁰⁴ Fibrous areas with bizarre tumor cells are also present. Sometimes the cytoplasmic vacuolation is insignificant, making it difficult to differentiate from other pleomorphic sarcomas, particularly on biopsy.³⁰³ A lipid stain sometimes helps in these cases. The dermal pleomorphic liposarcoma (discussed previously) showed small groups of neoplastic lipoblasts that expressed cytoplasmic and nuclear calretinin, which is said to be absent in the clear cell variant of atypical fibroxanthoma.²⁷⁰ In other cases of pleomorphic liposarcoma, lipogenic areas have been focally S100 positive in half, whereas nonlipogenic areas have shown focal reactivity in some cases for SMA, desmin, and CD34.³⁰⁴ Multivacuolated, 'mulberry' lipoblasts with markedly atypical nuclei labeling for S100 is a key feature allowing distinction from other pleomorphic sarcomas. A study of cutaneous and subcutaneous pleomorphic liposarcomas found a low incidence of *MDM2* gene amplification, suggesting that most superficial examples of this tumor are unrelated to well-differentiated or 'dedifferentiated' liposarcoma, which would be expected to express that amplification.³⁰⁵

Inflammatory cells are sometimes prominent in the stroma of pleomorphic liposarcoma (*inflammatory liposarcoma*). Rarely, an extensive lymphoplasmacytic infiltrate may be seen in the other variants of liposarcoma.²⁹⁷ Another histological 'variant' of pleomorphic liposarcoma is the so-called '*dedifferentiated liposarcoma*', which includes a well-differentiated (lipoma-like) component and dedifferentiated areas resembling malignant fibrous histiocytoma or myxofibrosar-

Figure 35.14 Pleomorphic liposarcoma. (A) Many vacuolated lipoblasts are present. (B) Another case. There are no vacuolated cells in this field. (H&E)

coma.³⁰⁶⁻³⁰⁹ It is genetically related to the well-differentiated liposarcoma rather than the pleomorphic liposarcoma because both the dedifferentiated and the well-differentiated liposarcoma express *MDM2* and *CDK4*.^{282,283,286} A variant of dedifferentiated liposarcoma with meningotheial-like whorls has been reported. The whorls represent a mesenchymal proliferation that may undergo myofibroblastic or osteoblastic differentiation.^{310,311} The whorls do not represent meningotheial differentiation.³¹⁰ Dedifferentiation can also occur in myxoid liposarcomas.³¹² Dedifferentiated liposarcomas have a variable course.^{306,308} In one series, nearly half of all liposarcomas showed p53 immunostaining.³¹³ Tumor size, grade, and histological subtype are predictors of metastasis in soft tissue liposarcomas.³¹⁴

The **dermal liposarcoma** may have unusually high-grade features resembling the pleomorphic liposarcoma. Myxoid, round cell, and well-differentiated variants have also been described. Despite these cytological features, metastases have been recorded in only one case of dermal liposarcoma,²⁷¹ almost analogous to other dermal sarcomas.^{269,292}

The **lipoleiomyosarcoma** is a well-differentiated liposarcoma with focal areas of smooth muscle differentiation or a dedifferentiated liposarcoma having smooth muscle differentiation in the dedifferentiated zones.³¹⁵

Liposarcomas must be distinguished from the changes seen in **massive localized lymphedema** of the morbidly obese, which is characterized by a large, ill-defined mass composed of mature fat interrupted by expanded connective tissue septa showing edema and neovascularization at the interface between fat and septa.^{166,316}

Electron microscopy

Liposarcomas are composed of cells showing lipoblastic differentiation with lipid droplets, micropinocytotic vesicles, glycogen, external

lamina, and intermediate filaments.³¹⁷ Most tumors contain lipid-free, poorly differentiated mesenchymal cells and cells resembling early lipoblasts with non-membrane-bound lipid vacuoles.³¹⁷

TUMORS OF SMOOTH MUSCLE

Smooth muscle is found in the skin in three distinct settings: the arrector pili muscles; the walls of blood vessels; and the specialized muscle of genital skin, which includes the scrotum (dartos muscle), vulva, and nipple (areolar smooth muscle). Each of these sources of smooth muscle can give rise to benign tumors, resulting in three categories of cutaneous leiomyoma: piloleiomyoma, leiomyoma of genital skin, and angioleiomyoma.¹⁻³ The rare leiomyoma of deep soft tissue and the case reported as 'leiomyomatosis' on the basis of numerous large and widespread tumoral masses of smooth muscle are additional categories.^{4,5} Leiomyomas of the scrotum and vulva show some histopathological differences from piloleiomyomas and leiomyomas of the nipple. These differences are highlighted later.

For completeness, note that smooth muscle has also been reported, rarely, in organoid⁶ and blue nevi.⁷ It has been reported as the only stromal component in a folliculosebaceous cystic hamartoma.⁸

LEIOMYOMA

Leiomyomas derived from the arrector pili muscle (*piloleiomyomas*, *pilar leiomyomas*) are more often multiple than solitary. Multiple lesions usually have their onset in the late second or third decade of life. They present as multiple, firm, reddish-brown papulonodules with a predilection for the face,⁹ back, and extensor surfaces of the extremities.¹⁰ Several hundred lesions may be present. They may cluster to form plaques,¹¹⁻¹³ which usually involve more than one area of the body.^{14,15} Rarely, tumors are zosteriform or symmetrically distributed,^{16,17} suggesting a nevroid condition, and these cases have been designated 'nevus leiomyomatosus systematicus'.¹⁸ Some of these cases probably represent a type 2 segmental manifestation of cutaneous leiomyomatosis.¹⁹ Some of the multiple cases are familial, with an autosomal dominant inheritance.^{20,21} There is a report of identical twins being involved.²² Multiple leiomyomas have been associated with uterine leiomyomas in some females (see later). Multiple piloleiomyomas may occur on the breast, away from the nipple. It has been suggested that mechanical stretching in large pendulous breasts may play an etiological role.²³ Erythropoietic activity of the tumors is a rare finding.²⁴ Minor trauma or exposure to cold temperatures may lead to severe pain in the tumors.^{11,25,26} Pruritus has been described with multiple piloleiomyomas.²⁷

Solitary piloleiomyomas,^{28,29} which are infrequently painful, are usually slightly larger than those found in patients with the multiple form, sometimes reaching 2 cm or more in diameter. Rarely, they are present at birth.^{30,31} There has been a female preponderance.

There are only sparse reports of *leiomyoma of the nipple*^{14,32} in the dermatopathological literature. Multiple lesions on both nipples are extremely rare.³³ Leiomyomas of genital skin are quite uncommon, with only small numbers of scrotal and vulval lesions reported.^{14,32,34-36} *Scrotal leiomyomas* present as firm, solitary asymptomatic nodules, measuring 1-14 cm in diameter.³⁷ *Vulval leiomyomas* usually arise in the labia majora.^{32,36} They usually measure 1-5 cm in diameter. Most are asymptomatic.

Histopathology

Piloleiomyomas are circumscribed non-encapsulated tumors, centered on the dermis.^{14,15} An overlying zone of uninvolved subepidermal tissue (so-called 'grenz zone') is usually present, and there may be some flattening of the epidermis. Epidermal hyperplasia was present in more than 50% of cases in one series.² The tumor is composed of bundles of smooth muscle arranged in an interlacing and sometimes a whorled pattern (Fig. 36.1). The cells have abundant eosinophilic cytoplasm and elongated nuclei with blunt ends. Nuclear palisading and the formation

of Verocay bodies was reported in one case.³⁸ Granular cell change is a rare variant.³⁹ There are usually no mitoses in the pilar variant. However, multiple atypical piloleiomyomas have been described in the setting of familial leiomyomatosis. These lesions featured large, bizarre nuclei with irregular contours, smudged chromatin, and pseudoinclusions; rare mitotic figures were also seen.⁴⁰ A relationship to symplastic leiomyoma was suggested.⁴⁰ Long-term follow-up was suggested because there has been a case of cutaneous leiomyosarcoma arising in a symplastic piloleiomyoma.⁴¹ Tumors of long standing may have fibrous tissue in the stroma, and occasionally this shows focal hyalinization.³² Osseous metaplasia is rare.⁴² Focal stromal myxoid change and small lymphoid collections have been noted. Hair follicles are sometimes found surviving within the tumor.¹⁴ The smooth muscle nature of the cells can be confirmed with the Masson trichrome stain or the use of immunoperoxidase markers for smooth muscle, such as vimentin, smooth muscle actin (SMA), desmin, and caldesmon.⁴² SMA is more specific for smooth muscle than panactin HHF35.⁴³ Lesions on the nipple are estrogen and progesterone receptor positive; both receptors are also found in normal subareolar muscle.⁴⁴ A Bodian stain has shown increased numbers of nerve fibers interlacing with the muscle fibers and also in the surrounding tissue.¹⁵

Dermoscopy of piloleiomyoma shows changes similar to those of dermatofibroma, including a central hypopigmented area and a delicate peripheral pigmented network. Some lesions also show a circular or elongated hyperpigmented structure within the central hypopigmented area; the latter could be due to focally compact hyperkeratosis or related to scratching.⁴⁵

Scrotal leiomyomas often have ill-defined or focally infiltrative margins, differing from the circumscribed tumors of pilar origin. Scrotal lesions are often more cellular with occasional mitoses. Symplastic features have been reported in all types.^{32,46-48} Clear cell and granular cell variants are rare.⁴⁹ Lymphoid aggregates are sometimes present. Dartoic muscle is seen adjacent to the tumor. Male genital leiomyomas may express androgen receptors.⁵⁰

Vulval leiomyomas are usually of spindle cell type, although rare epithelioid and myxoid variants occur.^{32,51} Sparse mitoses may be present. Stromal hyalinization is found in nearly half of the cases. Small fascicles of spindle cells may be trapped in these hyaline areas, producing a plexiform appearance.³² The majority of cases express estrogen and progesterone receptors,⁵¹ a feature not found in pilar lesions.⁵²

Differential diagnosis

Smooth muscle hamartoma differs from leiomyoma by having discrete bundles of smooth muscle fibers set in dermal collagen (see later). The multiple papular variant of pilar leiomyoma not infrequently exhibits small bundles of collagen between the smooth muscle bundles, but usually the collagen is not as plentiful as it is in smooth muscle hamartoma.⁵³ Piloleiomyomas sometimes show a resemblance to other benign spindle cell tumors of skin, including dermatofibroma or neurofibroma. However, the morphologic characteristics of the cells and their nuclei often permit distinction. In contrast to leiomyomas, dermatofibromas may have a significant inflammatory component, show xanthomatization, and may possess Touton-like multinucleated giant cells. The 'buckled', S-shaped nuclei of neurofibromas are distinctly different from the blunt-ended, cigar-shaped nuclei of leiomyoma. Immunohistochemistry can be useful in difficult cases because of the positivity for smooth muscle markers in leiomyomas, the factor XIII predominance in dermatofibromas, and the expression of S100 protein and other neural markers in neurofibromas. Both dermatomyofibromas and dermatofibromas with a myofibroblastic component can show positivity for smooth muscle actin, but unlike leiomyomas, they are usually negative for desmin. Rarely, piloleiomyomas with palisading or Verocay body formation may resemble neurilemmoma, but a lack of encapsulation, as well as the cytologic features and negativity for neural markers, should help in the diagnosis. Myxoid leiomyoma of the vulva has been

Figure 36.1 (A) Leiomyoma. (B) The reticular dermis is replaced by interlacing bundles of smooth muscle cells. (H&E)

confused with aggressive angioleiomyoma, and cells of the latter tumor may have both actin and desmin positivity (see previous discussion). However, the presence of interlacing cells with characteristics of smooth muscle cells is a distinctive feature of myxoid leiomyoma.⁵⁴ The cellular variant of neurothekeoma features intradermal nests and fascicles of epithelioid to spindle-shaped cells that are positive for smooth muscle actin. These cells have also been reported to be positive for NKI/C3 and neuron-specific enolase (weakly) and negative for desmin. Nevertheless, it has been suggested that cellular neurothekeoma may actually represent a variant of piloleiomyoma.⁵⁵ Superficial leiomyosarcomas can be distinguished from leiomyomas by their increased cellularity and pleomorphism. In addition, leiomyosarcomas display greater degrees of mitotic activity (usually more than two mitoses per 10 high-power fields (hpf), in contrast to the less than one mitosis per 10 hpf expected in leiomyomas), and they often show atypical mitotic figures. The sensitivity for finding mitotic figures can be enhanced with the use of the mitotic marker phosphohistone-H3 (PHH3).⁵⁶

CUTANEOUS AND UTERINE LEIOMYOMAS

The syndrome of multiple cutaneous and uterine leiomyomas (Reed syndrome, leiomyomatosis cutis et uteri; OMIM 150800) is a rare autosomal dominant disorder resulting from a germline mutation in the fumarate hydratase (*FH*) gene, which maps to chromosome

1q42.3–q43.^{24,57–61} Fumarate hydratase is an enzyme that functions as part of the Krebs cycle; it converts fumarate to malate.^{62,63} The gene may also have tumor suppressor functions. Many distinct mutations have been reported.⁶⁴ This syndrome can also be associated with type II papillary renal cell carcinoma and renal collecting duct carcinoma.^{61–66} Other morphological patterns have been described.⁶⁷ Leiomyosarcoma of the uterus is a rare complication.⁶⁴

The cutaneous lesions usually present in the second and third decades. They usually precede the diagnosis of uterine leiomyomas, which are often painful.⁶⁸ Nearly all women with multiple cutaneous leiomyomas have early onset uterine leiomyomas.⁶⁹ The G354R mutation predisposes patients to uterine leiomyomas without skin leiomyomas.⁶⁸ Males with *FH* mutations also have cutaneous leiomyomas.⁶⁴

Histopathology

All cutaneous leiomyomas in this syndrome are of pilar origin. They are localized to the upper two-thirds of the reticular dermis. Some are well circumscribed and nodular, but most are diffuse in arrangement.

ANGIOLEIOMYOMA

Angioleiomyoma usually presents as a solitary, slow-growing nodule on the extremities, particularly the lower leg, of middle-aged individuals.^{70,71} A rare example of congenital cutaneous angioleiomyoma has

been described.⁷² Digital lesions are rare.^{73,74} There is a female preponderance.^{75,76} More than half the lesions are painful or tender, but this feature is usually absent in those found on the face and upper trunk.^{70,77,78}

Multiple subcutaneous angioleiomyomas have been reported in a patient with AIDS.⁷⁹ Epstein-Barr virus was demonstrated in the nuclei of the smooth muscle cells.⁷⁹

The tumors are firm, gray-white round to oval nodules in the lower dermis and subcutis.⁸⁰ They are usually less than 2 cm in diameter. Most authors assume that they arise from veins, although some may be hamartomas.⁷⁶ A rare intravascular variant has been reported.⁸¹

Surgical excision is curative.

Histopathology

The tumor is usually well circumscribed with a fibrous capsule of variable thickness and completeness (Fig. 36.2). The main component is smooth muscle, which is present as interlacing bundles between the numerous vascular channels.^{70,76,80} Most of the vessels have several layers of smooth muscle in the walls that often merges peripherally with the intervascular fascicles (Fig. 36.3). Sometimes there are large sinusoidal vessels with little smooth muscle in their walls. Small slit-like channels are sometimes present. Most vessels have only scant and scattered elastic fibers in their walls.

The stroma contains varying amounts of fibrous tissue, and in approximately one-third of cases there is a sparse lymphocytic

infiltrate. Myxoid change is quite common in the stroma, particularly in the larger tumors.⁷⁵ The presence of fat in a few cases has led to suggestions of a hamartomatous origin;⁷⁶ a designation of '**angiomyolipoma**' can be used for these cases, which also contain fat (Fig. 36.4).⁸²⁻⁸⁷ The HMB-45 is negative in cutaneous tumors, in contrast to the finding in renal lesions.^{88,89} For these reasons, cutaneous angiomyolipomas should be regarded as an angioleiomyoma with fat.^{90,91} The term '**myolipoma**' is used for the rare tumors containing smooth muscle and adipose tissue but no vascular component.⁹² Uncommon changes include thrombosis of vascular channels, focal calcification,⁹³ stromal hemosiderin, and hyalinization of vessel walls. Nuclear palisading, producing Verocay-like bodies, is a rare occurrence.⁹⁴ Nerve fibers are only seen occasionally.¹ An angioleiomyoma arising in a histiocytoma has been reported.⁹⁵

In a review of 562 cases, three histological variants were described: a *solid type*, in which smooth muscle bundles surround numerous small slit-like channels; a *cavernous type*, with dilated vascular channels, the walls of which are difficult to distinguish from the intervascular smooth muscle; and a *venous type* with thick-walled vessels that are easily distinguished from the intervascular smooth muscle.⁷⁶ Using this classification, a more recent study found that of 122 cases, 74 were of

Figure 36.2 (A) Angioleiomyoma. (B) The smooth muscle bundles are admixed with small blood vessels. (H&E)

Figure 36.3 Angioleiomyoma. In this case, the individual vessels are thick walled; their outer layers of smooth muscle merge with the intervascular muscle fascicles. (H&E)

Figure 36.4 Angiomyolipoma. There is an admixture of blood vessels, smooth muscle, and adipocytes. (H&E)

solid type, 11 were cavernous, and 37 were venous in type.⁷⁸ Another variant is the *epithelioid* type, which is composed of cells with round to oval nuclei and a moderate amount of finely granular eosinophilic cytoplasm with occasional vacuoles.⁹⁶ An epithelioid variant with clear cell change has also been reported.⁹⁷ The *pleomorphic* type has marked nuclear pleomorphism but only rare or absent mitoses. There is some resemblance to the symplastic change seen in uterine leiomyomas.^{98–100}

In the series of 122 cases (mentioned previously), all cases were diffusely positive for actins (α -smooth muscle actin and HHF35) and calponin and diffusely or focally positive for h-caldesmon.⁷⁸ Desmin was diffusely positive in three-fourths of solid-type angioleiomyomas, half of the venous type, but only 18% of the cavernous type.⁷⁸

Differential diagnosis

Angioleiomyomas with palisading, resembling Verocay body formation, may resemble neurilemmoma, but cytologic details (e.g., angiocentricity, cytoplasmic myofibrils, and nuclear features) and special stains (e.g., PTAH, actin, and desmin) should permit correct identification. There can be a close histological resemblance of cases with a concentric perivascular arrangement to myopericytoma – a finding noted previously by Mentzel *et al.*¹⁰¹ In contrast to angioleiomyomas, most myopericytomas are negative for desmin, although they stain for the actins and calponin and, with one exception, also h-caldesmon.⁷⁸

SMOOTH MUSCLE HAMARTOMA

The smooth muscle hamartoma is a rare, usually congenital, hyperplasia of dermal smooth muscle fibers that presents as a flesh-colored or lightly pigmented plaque up to 10 cm in diameter on the extremities or trunk.^{3,102–110} The scrotum and prepuce are rarely involved.^{111–114} Some of the scrotal cases appear to represent acquired smooth muscle hypertrophy in response to chronic lymphedema.¹¹⁵ Within the plaques, small gooseflesh-like papules may be discernible, and these may transiently elevate when rubbed (pseudo-Darier's sign).^{116–118} This phenomenon of spontaneous, often asymptomatic, undulations of muscle fibers is known as myokymia. It may be the presenting sign of congenital smooth muscle hamartoma.¹¹⁹ A rare linear variant with perifollicular papules has been reported.¹²⁰ Hairs are usually more prominent in the skin of the affected site, being slightly longer and thicker than in the adjoining skin.¹²¹ A more generalized variant with prominent skin folds has been reported as a 'Michelin tire baby'.^{122–126} Follicular dimpling and hypertrichosis may be present in this generalized variant.¹²⁷ Multiple lesions have been described in three members of the same family.¹²⁸ Another case has been reported of multiple congenital familial smooth muscle hamartomas in two siblings.¹²⁹

Smooth muscle bundles, indistinguishable from those seen in this condition, may also occur in Becker's nevus,^{130–132} and this has led to some controversy about the relationship of these two entities.^{116,121} Becker's nevus has its onset in adolescence, with invariable hyperpigmentation and hypertrichosis. Reports of patients with the clinical features of smooth muscle hamartoma that developed in late childhood¹³³ or early adulthood^{134–136} suggest that Becker's nevus and smooth muscle hamartoma belong at different poles of the same developmental spectrum, involving hamartomatous change to the pilar unit and arrectores pilorum.^{108,137,138} A smooth muscle hamartoma has been reported in association with a melanocytic nevus; a Becker's nevus has also been present in one case.¹³⁹

Histopathology

There are well-defined smooth muscle bundles in the dermis, oriented in various directions. Some are attached to, or surround, hair follicles.^{108,116} Often, there is a thin retraction space around the bundles, separating them from the adjacent dermal collagen (Fig. 36.5). The

Figure 36.5 Smooth muscle hamartoma. (A) There are scattered smooth muscle bundles in the dermis. (H&E) (B) There is collagen between the smooth muscle bundles. (Masson trichrome)

smooth muscle bundles are clearly seen with the Masson trichrome stain. Bundles of nerve fibers may also be present.¹⁰⁷ These findings can be confirmed with appropriate immunohistochemical stains. The smooth muscle expresses desmin and smooth muscle actin.^{110,113,115} It is also positive with antibodies to smoothelin, a cytoskeleton protein found in smooth muscle cells with contractile capacity.¹⁴⁰ Smoothelin is found in arrector pili muscle and vessel walls of the deep vascular plexus, and it is not expressed in myofibroblasts or superficial dermal vessels as is the case with smooth muscle actin.¹⁴⁰ Interestingly, large numbers of CD34⁺ cells may be present in the stroma surrounding the smooth muscle bundles.¹⁴¹ They were not present in the acquired scrotal cases secondary to lymphedema.¹¹⁵ There is often slight elongation of the rete ridges of the overlying epidermis and mild basal hypermelanosis.¹³⁷

The smooth muscle hamartoma reported in a patient with the MLS syndrome (microphthalmia with linear skin defects) appeared to consist of hypertrophied arrectores pilorum muscle with some thinning of the epidermis and upper dermis.¹⁴²

A hamartoma composed of hyperplastic smooth muscle and blue nevus has also been reported; additional findings include junctional lentiginous melanocytic proliferation, acanthosis, and follicular induction.¹⁴³

Electron microscopy

Ultrastructural examination confirms the presence of normal smooth muscle cells in this lesion.^{121,138}

LEIOMYOSARCOMA

Primary cutaneous leiomyosarcomas are infrequent tumors that may arise in the dermis or subcutaneous tissue.^{144,145} Secondary leiomyosarcomas constitute a third category; they are exceedingly rare. Dermal and subcutaneous lesions have a different biological behavior (see later).

Well over 100 cases of *dermal leiomyosarcoma* have now been recorded.^{144,146} These tumors have a predilection for the extensor surfaces of the extremities^{144,145} and, to a lesser extent, the scalp¹⁴⁷ and trunk.^{148–152} Rare sites include the upper lip,¹⁵³ nipple,^{154,155} penis,^{156,157} scrotum,^{158,159} vulva,¹⁶⁰ a chronic venous stasis ulcer,¹⁶¹ and the face.^{28,162} There is a male predominance, and the average age of presentation is in the sixth decade. Childhood presentation is rare.^{163,164} Epstein-Barr virus-associated smooth muscle tumors, including leiomyosarcoma, are seen in immunocompromised individuals, and they comprise the second most common tumor group in children with HIV infection.¹⁶⁵ The tumors vary in size from 0.5 to 3 cm or more in maximum diameter. Subcutaneous extension is present in two-thirds of cases.¹⁴⁴ Pain or tenderness is present in some.¹⁴⁵ Occasionally, there is a history of previous injury to the site.^{145,148} These tumors presumably arise from the arrector pili muscles, except for scrotal lesions, which derive from the dartos muscle.^{144,145} Cases arising in an angioleiomyoma,¹⁶⁶ in an organoid nevus (nevus sebaceus),¹⁶⁷ and in the scar of a previously excised leiomyoma have been reported.¹⁶⁸ Dermal leiomyosarcomas may recur locally in up to 30% of cases (10% in the author's experience), but metastases of confirmed cases are unknown.¹⁴⁴

The recurrence rate seems to be lower when wide surgical excision is carried out initially. A clearance of at least 3 cm should be obtained. Mohs surgery has been used for lesions on the face.¹⁶⁹

Subcutaneous leiomyosarcomas tend to be slightly larger at presentation and more circumscribed in outline.¹⁴⁵ They may also be tender or painful. They presumably arise from the smooth muscle in vessel walls.¹⁷⁰ They have a greater tendency for local recurrence (50–70%), and metastases to lung, liver, bone, and other sites occur in approximately one-third of cases.^{145,171,172} Assessment of the DNA content of the tumor cells by flow cytometry may be used to predict those with

metastatic potential.^{173–175} The most frequent genomic alterations in leiomyosarcomas involve losses in the 13q4–q21 region, but other chromosomal losses occur.¹⁷⁶ Malignant fibrous histiocytoma shares many of these genomic imbalances.¹⁷⁶

Secondary leiomyosarcomas are rare in the skin and arise from retroperitoneal and uterine primary lesions.¹⁷⁷ There are usually several dermal or subcutaneous nodules. There has been a predilection for the scalp and back.

Histopathology

Dermal leiomyosarcomas are irregular in outline, with tumor cells blending into the collagenous stroma at the periphery.¹⁷⁸ By definition, the major portion of the tumor is in the dermis, although subcutaneous extension occurs in two-thirds.¹⁴⁴ A superficial grenz zone is present in many. Ulceration and pseudoepitheliomatous hyperplasia are rare. There is usually some flattening of the rete ridges of the overlying epidermis.

Leiomyosarcomas are composed of interlacing fascicles of elongated spindle-shaped cells with eosinophilic cytoplasm and eccentric, blunt-ended (cigar-shaped) nuclei (Fig. 36.6). Rare variants with intracytoplasmic eosinophilic granules (*granular cell leiomyosarcoma*)^{39,179,180} or with epithelioid cells (*epithelioid leiomyosarcoma*)^{181,182} have been reported. Sometimes there is a suggestion of nuclear palisading. There is variable

Figure 36.6 Leiomyosarcoma. (A) The tumor is composed of plump spindle-shaped cells. (B) Scattered mitoses are present. (H&E)

Figure 36.7 Subcutaneous leiomyosarcoma. The lesion is quite cellular. (H&E)

nuclear pleomorphism, with at least one mitosis per 10 hpf in cellular areas. Pockets of greater mitotic activity (mitotic ‘hot spots’)¹⁸³ are found. Tumor giant cells are usually present in the less well-differentiated variants. Perinuclear halos are rare. Small lymphoid aggregates are sometimes present within the tumor,¹⁴⁴ but a dense infiltrate (*inflammatory leiomyosarcoma*) is quite rare.¹⁶³ Stromal sclerosis (*desmoplastic leiomyosarcoma*) is a rare phenomenon.^{162,184–186} The resemblance of this tumor to other desmoplastic tumors of the skin is striking, and immunohistochemistry is necessary for its diagnosis.¹⁸⁵ Arrector pili muscles are often prominent or hyperplastic, and in some cases transitions from normal to hyperplastic, to benign neoplastic, and to a frankly sarcomatous pattern occur.^{144,145}

In one large series, two predominant growth patterns were observed: nodular and diffuse (infiltrative).¹⁴⁶ Nodular tumors were usually quite cellular with nuclear atypia and many mitoses. Sometimes there were small foci of necrosis. Diffuse tumors were less cellular with well-differentiated smooth muscle cells and inconspicuous mitoses.¹⁴⁶

Subcutaneous leiomyosarcomas often extend into the lower dermis (Fig. 36.7). They frequently have a prominent vascular pattern;¹⁴⁵ vascular invasion is an adverse prognostic feature.¹⁷⁴ Small areas of necrosis are sometimes present. Deep variants with either a heavy inflammatory cell component¹⁸⁷ or osteoclast-like giant cells¹⁸⁸ have been reported. A myxoid and a pleomorphic variant have been reported in the deeper soft tissues.^{189–192}

Kraft and Fletcher analyzed a series of 84 cases of what they termed atypical intradermal smooth muscle neoplasms, confined to the dermis or with only very superficial subcutaneous extension. Most showed infiltrative growth patterns, with a mean mitotic rate of 4.7/10 hpf. Almost all were grade I by the Federation Nationale des Centres de Lutte Contre le Cancer (FNCLCC) grading system. Follow-up for a mean of 51 months showed no metastases or deaths.¹⁹³ There were some local recurrences, the most significant predictor of which was margin status. The authors consider ‘sarcoma’ an inappropriate designation for these lesions.¹⁹³

Secondary leiomyosarcomas are often multiple, spheroidal in outline, and sometimes present in vascular lumina.^{144,194}

Leiomyosarcomas of all three types will have myofilaments, demonstrated by the Masson trichrome stain. Reticulin stains show a fine reticulin network interspersed between adjacent fibers. A small amount of glycogen is usually present.¹⁹⁵ Immunoperoxidase preparations show the presence of vimentin, smooth muscle actin, and h-caldesmon.^{186,196} Desmin is present in approximately 70% of cases but is less common in the higher grade tumors.^{146,175} Pan-muscle actin (HHF35) is usually present. Cytokeratin, CD117, S100 protein, and factor XIIIa have

been demonstrated in a small number of cases.^{146,197–199} In the case of the cytokeratin marker MNF116, Iwata and Fletcher found positivity in 5 of 20 cutaneous cases; epithelial membrane antigen (EMA) was expressed in 9 of these cases.²⁰⁰ β -Catenin is not expressed.

Reliable criteria for malignancy remain to be established.¹⁸³ Usually accepted features include high cellularity, significant nuclear atypia, tumor giant cells, and at least one mitosis per 10 hpf. Tumor size of 5 cm or more is an adverse feature in subcutaneous tumors.²⁰¹ The cell–matrix adhesion protein migfilin is increased in the cytoplasm of tumor cells in the progression of leiomyosarcomas from low to high grade.²⁰² It is not found in normal smooth muscle cells.

Electron microscopy

Electron microscopy confirms the smooth muscle origin of the tumor cells, with numerous fine myofilaments in the cytoplasm, some marginal plaques, pinocytotic vesicles, glycogen, and a basal lamina surrounding individual cells.^{158,183} Junctional complexes are uncommon.¹⁸³ Some myofibroblasts may also be present.¹⁵⁹

Differential diagnosis

Tumor size, cellularity, atypia, and mitotic activity should usually permit a distinction from leiomyoma, although features of malignancy in leiomyosarcoma are occasionally subtle.^{162,186} Cutaneous leiomyosarcoma must often be differentiated from other malignant spindle cell tumors that develop in skin, including dermatofibrosarcoma protuberans and malignant fibrous histiocytoma. Subcutaneous varieties with vascular prominence may resemble hemangiopericytoma. Epithelioid leiomyosarcomas have a differential that includes malignant melanoma, epithelioid sarcoma, and primary or metastatic carcinomas. In most leiomyosarcomas, foci can be found that show recognizable smooth muscle differentiation; these morphologic clues can be supported by immunohistochemistry or ultrastructural examination. Although some dermal leiomyosarcomas express S100 protein, the neoplastic cells should express actins and give negative results for other melanocytic markers. The epithelioid leiomyosarcomas described by Suster were negative for S100 and HMB-45.¹⁸¹ Desmoplastic leiomyosarcoma must be distinguished from desmoplastic melanoma – a distinction that is obviously aided by the positivity for smooth muscle markers in the former. In a recent case of desmoplastic leiomyosarcoma, there were a few S100⁺ cells that most likely represented entrapped dendritic cells; obvious neoplastic cells were S100[−].²⁰³ In spindle cell or desmoplastic squamous cell carcinoma, tumor cells are usually positive for p63 and may express cytokeratins (e.g., 34 β E12).²⁰³ Immunohistochemical differentiation of epithelioid leiomyosarcoma and epithelioid sarcoma could potentially be difficult because both are positive for vimentin, and, as noted previously, some leiomyosarcomas are positive with certain cytokeratins and EMA, whereas a number of epithelioid sarcomas express muscle-specific actin. However, leiomyosarcomas also express smooth muscle actin, h-caldesmon, and (often) desmin, whereas the cells of epithelioid sarcoma are frequently positive for CD34.

TUMORS OF STRIATED MUSCLE

There is an exceedingly rare group of cutaneous tumors that contain either mature striated muscle or cells differentiating toward striated muscle as a major component of the lesion. Mature striated muscle is found in some parts of the face as a normal constituent,²⁰⁴ in rhabdomyomatous mesenchymal hamartoma (see later), in the accessory tragus (see p. 584), and in the first arch abnormality reported as dermatorynchus geneae (see p. 584). Rarely, a few striated muscle fibers may be present adjacent to developmental cysts of the head and neck. There is one report of skeletal muscle regeneration

presenting as an enlarging nodule on the lip following blunt trauma.²⁰⁵ Rhabdomyomas are usually found in the vicinity of the aerodigestive tract.²⁰⁶ Rarely, they occur elsewhere (see later). Malignant cells showing ultrastructural, immunohistochemical, and sometimes light microscopic differentiation toward striated muscle are a feature of rhabdomyosarcomas. Brief mention is also made of the malignant rhabdoid tumor, which has some histopathological similarities to a rhabdomyosarcoma but which is of uncertain histogenesis.

RHABDOMYOMATOUS MESENCHYMAL HAMARTOMA

This rare hamartoma of the deep dermis and subcutaneous fat was first described in 1986 as a *striated muscle hamartoma*.²⁰⁷ It has also been reported as *congenital midline hamartoma*.²⁰⁸ It may present as a solitary papule or nodule in a normal neonate or arise in the setting of multiple ectodermal/mesodermal abnormalities.²⁰⁹⁻²¹⁴ Such cases are called multiple rhabdomyomatous mesenchymal hamartomas.²¹⁵ Solitary lesions are usually midline in location on the head and neck. The chin is a common site;²¹⁶ the perianal region is rarely involved.^{217,218}

Histopathology

The polypoid tumors contain multiple bundles of normal-appearing striated muscle surrounded by fibrofatty tissue containing a few telangiectatic vessels.^{207,210} Smooth muscle as well as striated muscle was present in the lesion from the perianal region reported as a *cutaneous mesenchymal hamartoma with mixed myogenous differentiation*.²¹⁸ Numerous vellus hair follicles or folliculosebaceous structures are usually present (Fig. 36.8).²¹⁹ Lentiginous melanocytic hyperplasia was present in one case.²²⁰ It was not known if this was a component of the hamartoma or an inductive phenomenon.²²⁰ The worm-like, flesh-colored, cutaneous polyps that occur in the **disorganization syndrome** (OMIM 223200) lack striated muscle, a feature of multiple rhabdomyomatous mesenchymal hamartomas.²¹⁵

The subcutaneous tumor with desmin-positive spindle cells, reported as **pleomorphic hamartoma of the subcutis**, is of uncertain histogenesis.²²¹

RHABDOMYOMA

Two variants of rhabdomyoma have been described: the adult rhabdomyoma and the fetal rhabdomyoma.²²² The *adult rhabdomyoma* is a rare, benign neoplasm that usually occurs in the head and neck region.²²³ Rarely, it may arise elsewhere.²²⁴ Rhabdomyomas are well-circumscribed, soft tumors with a reddish-brown appearance. They may recur locally if incompletely excised. The *fetal rhabdomyoma* is found in both children and adults. It is located in various organs of the body. Only one case involving the skin has been reported.²²² It may develop in deeper tissues in the nevroid basal cell carcinoma syndrome.

Histopathology

Adult rhabdomyomas are composed of sheets of large polygonal cells with granular, eosinophilic cytoplasm. The cells are partly vacuolated due to their glycogen content. 'Spider-web' cells, with residual strands of cytoplasm between the vacuoles, and cells with cross-striations may both be present.²²³ The tumor cells stain strongly for desmin and myoglobin; some may stain weakly for S100 protein.²²⁴

Fetal rhabdomyomas are composed of immature striated muscle. Fascicular bundles of immature cells with oval to spindle-shaped nuclei

Figure 36.8 Rhabdomyomatous mesenchymal hamartoma. (A) This polypoid lesion contains vellus follicles and eccrine sweat gland coils. Bundles of skeletal muscle extend into the dermis (arrows). (B) At higher magnification, skeletal muscle bundles can be seen on the right, and portions of follicular epithelia can be seen on the left. (H&E)

are present.²²² Scattered among these bundles are elongated cells with rhabdomyoblastic differentiation.

RHABDOMYOSARCOMA

Rhabdomyosarcoma, a tumor composed of malignant cells showing some differentiation toward striated muscle, has a predilection for the head and neck region,^{225,226} the genitourinary tract, the retroperitoneum, and the soft tissues of the extremities. It is the most common soft tissue sarcoma of childhood. Rarely, rhabdomyosarcoma may present as a dermal nodule, particularly on the head or neck, usually as a result of the dermal extension of a lesion arising in the underlying soft tissues.²²⁷⁻²³⁰ Lesions of dermal origin are rare.^{231,232} A primary cutaneous presentation occurs in less than 1% of all rhabdomyosarcomas.²³³ Cutaneous rhabdomyosarcoma has a bimodal age distribution, involving children/teenagers and older adults.²³⁴

Rhabdomyosarcomas have been reported in patients with neurofibromatosis, in the basal cell nevus syndrome, and many years after radiotherapy.²³⁵ A female infant with Beckwith–Wiedemann syndrome (hypoglycemia, gigantism, macroglossia, and omphalocele) presented with an oral mass and blueberry muffin lesions; biopsies of both showed alveolar rhabdomyosarcoma.²³⁶

Specific chromosomal translocations involving chromosome 13 are consistently found in the alveolar subtype. In a recent case of alveolar rhabdomyosarcoma on the face of an adult, diagnosis was substantiated by the finding of *PAX3–FKHR* fusion gene transcripts in paraffin-embedded tumor tissue using reverse-transcriptase polymerase chain reaction.²³⁷ Fusion products can also be demonstrated by fluorescence *in situ* hybridization methods (Fig. 36.9). Chromosomal gains and losses have been reported in the embryonal form but not any diagnostic translocations.^{228,233}

Figure 36.9 FISH of alveolar rhabdomyosarcoma. This fluorescence *in situ* hybridization preparation shows joined red and green signals in tumor cells, representing *PAX3* and *FKHR*, respectively. (Image courtesy Mark R. Wick, M.D.)

Histopathology

There are three major histological subtypes of rhabdomyosarcoma: embryonal (including the botryoid variant) (Fig. 36.10), alveolar (Fig. 36.11),²³⁸ and pleomorphic.^{239,240} The spindle cell rhabdomyosarcoma is a rare variant of the embryonal type.²³⁰ Rhabdomyosarcomas may be composed of small round cells, spindle or polygonal cells, or large pleomorphic cells. Cross-striations are sometimes seen using the phosphotungstic acid–hematoxylin stain.

Immunoperoxidase techniques using monoclonal antibodies to vimentin, desmin, myogenin, myoglobin, MyoD1, Myf-4, and muscle-specific actin may be used to confirm the diagnosis.^{227,230,232} Amianthoid-like fibers (extracellular deposits representing collagen fibers, found in a variety of tumors and so named for a crystalline appearance like that of asbestos) have been found in a pleomorphic rhabdomyosarcoma developing after radiotherapy of an oral squamous cell carcinoma.²⁴¹ Myogenin and MyoD1 are very specific for striated muscle, but they may be negative in some pleomorphic rhabdomyosarcomas.⁴³ In one cutaneous embryonal rhabdomyosarcoma, the spindle cells stained for S100 protein.²²⁹ Some tumors, particularly the alveolar variant, express ALK protein.²⁴²

Figure 36.10 Embryonal rhabdomyosarcoma. Both botryoid and spindle cell subtypes have been reported in the skin. (H&E)

Figure 36.11 Alveolar rhabdomyosarcoma. This form of rhabdomyosarcoma is the one most frequently reported in skin. (H&E)

Differential diagnosis

The differential diagnosis of rhabdomyosarcoma is fairly broad. Small cell tumors can resemble metastatic neuroblastoma, lymphoma, melanoma, primitive neuroectodermal tumor, or small cell carcinoma. Pleomorphic tumors can mimic melanoma, pleomorphic liposarcoma, leiomyosarcoma, or malignant fibrous histiocytoma. Immunohistochemistry or electron microscopy can be helpful in differentiating among these tumors. Thus, in a retrospective immunohistochemical study of pleomorphic sarcomas, de Jong *et al.* found that a majority of tumors originally diagnosed as rhabdomyosarcoma were reclassified as malignant fibrous histiocytoma or leiomyosarcoma, whereas one tumor initially diagnosed as pleomorphic sarcoma was reclassified as a rhabdomyosarcoma.²⁴³

MALIGNANT RHABDROID TUMOR

Malignant rhabdoid tumors (OMIM 609322) were initially regarded as a subset of Wilms' tumor of the kidney showing rhabdomyosarcomatous differentiation.²⁴⁴ Subsequent studies have not confirmed this, and their histogenesis is currently uncertain. Tumors of similar morphology to the renal lesions have been reported in the skin.²⁴⁵⁻²⁵⁴ Cutaneous lesions are highly aggressive neoplasms often present at birth, although adult cases have been reported.²⁵⁵ Sometimes this rhabdoid phenotype is seen in conjunction with other cutaneous tumors.²⁵⁵ The average survival following diagnosis is less than 6 weeks.²⁵⁶ Genetic studies show a consistent pattern of abnormalities of chromosome 22q11, involving deletions and/or translocations.^{256,257} The affected gene is *IN11*, also known as *SMARCB1*.²⁵⁸ Familial cases involving multiple generations have resulted from mutations in this gene.²⁵⁸

There is a report of two children with papulonodular skin lesions, present at birth, who subsequently developed malignant rhabdoid tumors, in one case in contiguity. The term 'neurovascular hamartoma' was used for these lesions composed of bland spindle cells in a vascular stroma.²⁵⁹ Another case developed adjacent to a 'benign myofibromatous proliferation'.²⁶⁰

Histopathology

The tumor is composed of sheets of polygonal cells with abundant hyaline eosinophilic cytoplasm and a peripherally displaced vesicular nucleus. Mitotic activity is prominent, and there are usually areas of tumor necrosis (Fig. 36.12).²⁴⁵

The cells invariably express vimentin and cytokeratins AE1/AE3 and/or CAM5.2. They often show strong focal to diffuse membranous staining for EMA.^{256,261} Focal positivity for muscle-specific actin and desmin may occur.²⁵⁶

Differential diagnosis

Malignant rhabdoid tumor has some morphological and immunohistochemical features in common with epithelioid sarcoma (see p. 1007), although the cells in epithelioid sarcoma do not contain rhabdoid filamentous masses.^{245,246} Distinguishing the two may depend on the patient's age, the clinical location of the tumor, and the overall microscopic configuration. Occurrence on the forearm or hand of a young adult, and microscopic features of multinodularity and central necrosis mimicking a palisaded necrobiotic granuloma, would favor epithelioid sarcoma. Loss of *SMARCB1/IN11* protein expression has also been reported in epithelioid sarcoma, but the frequency of this gene alteration is lower in proximal-type epithelioid sarcoma than in malignant rhabdoid tumor; furthermore, the mechanism of loss of protein expression may differ between the two tumors.²⁶² Poorly differentiated squamous cell carcinoma and malignant melanoma can also resemble

Figure 36.12 Malignant rhabdoid tumor. Polygonal cells show eosinophilic cytoplasm and rounded, vesicular nuclei with distinct nucleoli. Some tumor cell necrosis is evident. (H&E)

malignant rhabdoid tumor. Rhabdoid differentiation has been reported in some malignant nerve sheath tumors.²⁶³

TUMORS OF CARTILAGE

Cartilage can be found in the skin in hamartomas (see p. 430), in certain tumors (e.g., chondroid syringomas), and in chondromas and osteochondromas. The latter two entities are discussed here, together with the morphologically similar tumor known as parachordoma. The extraskeletal myxoid chondrosarcoma is a deep soft tissue tumor and beyond the scope of this book.²⁶⁴ A chondroblastoma, presenting as a subungual mass on a toe, has also been reported.²⁶⁵

CHONDROMA

True cutaneous chondromas, without bony connection, are exceedingly rare.^{266,267} They occur most commonly on the fingers, but they have been recorded at other sites, such as the ear²⁶⁸ and nose.²⁶⁸ Multiple lesions were present in one patient, who had a suggested autosomal dominant mode of inheritance.²⁶⁸

Histopathology

Chondroma is a well-circumscribed expansile tumor composed of single and grouped chondrocytes embedded in a cartilaginous matrix. It usually produces effacement of the epidermal rete ridge pattern (Fig. 36.13).²⁶⁸ The cells exhibit reactivity for S100 protein.

SUBUNGUAL OSTEOCHONDROMA

Subungual osteochondroma (exostosis) is a fairly common, often painful tumor occurring on the distal phalanx of a digit, usually the great toe.²⁶⁹⁻²⁷⁴ They may be misdiagnosed initially.²⁷⁵

Excision of the lesion is the usual treatment.²⁷⁶

Histopathology

The lesion consists of a base of mature trabecular bone with a proliferating cap of mature cartilage.²⁷³ Osteogenesis occurs by endochondral ossification (Fig. 36.14).

Figure 36.13 Chondroma. (A) At low magnification, this is a well-circumscribed lesion with fibrosis and foci of calcification. Cartilaginous tissue can be seen at the lower right (arrow). (H&E) (B) Higher magnification shows a central zone that contains hyaline cartilage and calcium deposition. (H&E)

Figure 36.14 Subungual osteochondroma. This image shows a cap of hyaline cartilage with underlying trabecular bone. (H&E)

Differential diagnosis

Subungual osteochondroma and exostosis have some similarities, but there are clinical and histopathologic differences that have led some authors to conclude that they are distinctive. In contrast to subungual osteochondromas, exostoses occur in females more often than in males, are often preceded by trauma or infection, and develop in the distal tuft of the phalanx rather than the epiphyseal line. Exostoses possess a cap of fibrocartilage rather than hyaline cartilage, which is to be expected because the distal phalangeal tuft develops through enchondral ossification. Microscopically, this fibrocartilaginous cap is hypercellular, with plump nuclei and multinucleation. This stands in contrast to the cartilaginous cap of osteochondroma, in which chondrocytes are arranged in a manner resembling a normal growing epiphysis.²⁷⁷

PARACHORDOMA

Parachordoma is an exceedingly rare soft tissue neoplasm with a superficial resemblance to a chordoma. It develops on the extremities adjacent to a tendon, synovium, or bone, unlike chordoma, which is axial in location.^{278,279} Parachordomas are slow-growing tumors with occasional late recurrence. Cases with reported metastasis have not been convincing.²⁸⁰

Chordomas may develop in the skin by direct extension from an underlying sacrococcygeal tumor or by distant metastasis (see p. 1126). The term chordoma cutis has been used for such cases.²⁸¹

Histopathology

As in chordomas, there are strands and cords of vacuolated (physaliphorous) cells set in a myxoid stroma (Fig. 36.15).²⁷⁸ The cells stain for S100 protein, vimentin, and EMA.^{279,280} Parachordomas are strongly positive for cytokeratin (CK) 8/18 but not for CK1/10, -7, and -20.²⁸⁰ Extraskel-etal myxoid chondrosarcoma is negative for all cytokeratins.^{280,282}

TUMORS OF BONE

Mature bone may be found in the skin in the various forms of osteoma cutis (see p. 427). True neoplasms with differentiation toward bone

Figure 36.15 (A) Parachordoma. (B) Nests of vacuolated cells are set in a fibromyxoid stroma. (H&E)

(osteosarcoma) are exceedingly rare in the skin.^{283–285} A case purporting to be a cutaneous osteoblastoma has been reported.²⁸⁶

OSTEOSARCOMA

Osteosarcoma (osteogenic sarcoma) of the skin may arise *de novo* or within heterotopic bone.^{283,287–289} An origin from underlying bone or

Figure 36.16 Osteosarcoma. This is a highly cellular area containing spindle cells with elongated, hyperchromatic nuclei. These features often resemble those of other soft tissue sarcomas. (H&E)

metastasis from a primary lesion elsewhere must be excluded. Primary osteosarcoma of the skin can recur locally²⁸⁵ and/or spread to the lungs and other organs.^{283,284,290}

Histopathology

The tumor may be found in the dermis and/or the subcutis.²⁹¹ Ulceration often occurs. Highly cellular areas composed of spindle cells with scant eosinophilic cytoplasm and elongated hyperchromatic nuclei are usually present (Fig. 36.16), in addition to foci of chondroid and osteoid differentiation.²⁸⁹ The tumor cells are positive for vimentin but negative for S100 protein and cytokeratins.

INTRODUCTION

Neural tumors are an important category of cutaneous tumors. Although the vast majority of them can be diagnosed without difficulty, there are cases that require distinction from other spindle cell tumors, including melanoma. Markers are still being sought that will allow a reliable distinction between neural tumors and spindle cell melanomas.

Cutaneous neural tumors arise from, or differentiate toward, one or more elements of the nervous system. Most of the tumors found in the skin and subcutaneous tissue are derived from peripheral nerves or their neurocutaneous end organs. There are three principal cells comprising the sheath of peripheral nerves: the perineurial cell, the Schwann cell, and the fibroblast. Perineurial cells, which differ from Schwann cells by having no basement membrane, give rise to the perineurioma. Schwann cells give rise to the three main types of cutaneous neural tumors: neuromas, schwannomas (neurilemmomas), and neurofibromas. The tumors differ from one another by having a different proportion and arrangement of the various constituents of a peripheral nerve – Schwann cells, axons, fibroblasts, and supporting stroma. Although Schwann cells are generally viewed as neuroectodermal cells derived from the neural crest, it has been suggested that they may be of mesenchymal origin.¹ The perineurial cell may also be of neural crest derivation.²

The other categories considered in this chapter are the herniations and heterotopias of glial and meningeal cells, giving rise to nasal gliomas, cutaneous meningiomas and related heterotopias, and the neuroendocrine carcinoma (Merkel cell tumor), which may be derived from another neural crest derivative – the Merkel cell. This cell subserves a neurosensory function in the skin. Merkel cell hyperplasia has been found in many settings, including sun- and radiation-damaged skin, as well as in some tumors of follicular origin.³

Before considering the various tumors, it is worth noting a comparatively recent paper reviewing cutaneous innervation.⁴ Itching and pain are symptoms of many of the conditions described in this book, and an understanding of the mechanisms involved is of some relevance.

NERVE SHEATH TUMORS

The principal tumors in the nerve sheath category are neuromas, schwannomas (neurilemmomas), neurofibromas, and their variants. Because malignant peripheral nerve sheath tumors are rare, and often deep-seated, only a brief account is given. The granular cell tumor (myoblastoma) is possibly of Schwann cell origin and is also included. Nerve sheath tumors express both S100 protein and myelin basic protein.⁵ The reaction for these substances is less intense in the malignant peripheral nerve sheath tumors.⁵ Epithelial membrane antigen is present in the perineurial cell, the capsule of some nerve sheath tumors (see later), and in the nerve sheath myxoma.⁶ Perineurial cells also express vascular endothelial cadherin.⁷ The human progenitor cell antigen CD34 is present in a dendritic cell within the endoneurium of normal nerves,⁸ as well as in neurofibromas, Antoni B areas of neurilemmomas, and dermatofibrosarcomas.^{9,10}

NEUROMAS

Neuromas are nerve sheath tumors in which the ratio of axons to Schwann cell fascicles approaches 1:1.¹¹ There are four distinct clinicopathological groups: traumatic neuromas, rudimentary polydactyly, solitary neuromas, and neuromas associated with the multiple endocrine neoplasia syndrome (type 2b). Ganglioneuromas are also considered here.

Traumatic neuroma

Traumatic neuromas result when a nerve is sectioned or traumatized in some way, and continuity cannot be re-established.¹² They are therefore found at sites of trauma, in scars, and in amputation stumps.¹³ One case followed a human bite.¹⁴ Traumatic neuromas are usually firm, oval, pea-sized nodules in the subcutis or deeper soft tissues.¹² They may be painful. Traumatic neuromas may represent a locus minoris resistentiae that may be used by neoplastic cells to spread outside of the main tumor mass.¹⁵ This is an exceedingly rare phenomenon.

Histopathology¹³

Traumatic neuromas are composed of an irregular arrangement of nerve fascicles embedded in fibrous scar tissue. There may be concentric condensations of fibrous tissue around individual fascicles, giving the appearance of multiple separate nerves (Fig. 37.1). Intraepithelial nerve fibers were present in one traumatic neuroma removed from the lower lip.¹⁶ Perineurial cells, which contain epithelial membrane antigen, surround each fascicle, in contrast to solitary circumscribed neuromas, in which only the peripheral capsule contains these cells.¹⁷ A Bodian stain will confirm the presence of numerous axons (Fig. 37.2).

Figure 37.1 Traumatic neuroma composed of nerve fascicles separated by thin septa of fibrous tissue. (H&E)

Figure 37.2 Traumatic neuroma. Numerous axons are present. (Bodian preparation)

As in most neural tumors, mast cells are scattered throughout. Smooth muscle actin positivity has been found, and expression intensity of α -smooth muscle actin correlates with pain in traumatic neuromas as assessed by the visual analog scale for pain.¹⁸

Electron microscopy

Studies have shown that each fascicle is ensheathed by multiple laminae of perineurial cells.¹⁹ Furthermore, there is wide variation in the size of the axons.¹⁹

Rudimentary polydactyly

The term 'rudimentary polydactyly' is applied to a small nodular tumor that is found rarely near the base of the fifth finger, along its ulnar border.^{20–22} Most cases present in neonates or in childhood; presentation in adult life is uncommon.²³ The traditional view – that it is a variant of amputation neuroma at the site of a supernumerary sixth digit, presumed to have undergone spontaneous autoamputation – has been challenged (Fig. 37.3).²⁴ It has been suggested that such lesions are neural malformations unrelated to a supernumerary digit.²⁴ A lesion with similar histology has been reported on the penis.²⁴ A family history of polydactyly is sometimes present.²³

Figure 37.3 Rudimentary polydactyly. (A) This lesion clearly arose at the site of a supernumerary digit. The portion on the right of the figure is the accessory digit, with a cartilaginous center (arrow). On the left is the neural lesion (either traumatic neuroma or neural malformation). (B) Higher power view showing detail of the neural lesion. (H&E)

Primary suture ligation of supernumerary digits in infancy may lead to the later development of a true amputation neuroma. Surgical excision of the lesion with high transection of the accessory digital nerve prevents the later development of amputation neuromas.²⁵

Histopathology

There are numerous bundles of nerve fibers embedded in connective tissue in the upper dermis, and in dermal papillae (Fig. 37.4). Many oval corpuscles, resembling small Meissner corpuscles, are also present. This latter feature, together with the indefinite outline and the position in the upper dermis, differs from the usual traumatic neuroma.^{21,26} This supports the view that the traditional explanation for these lesions is incorrect.²⁴

Electron microscopy

There are normal Merkel cells along the basal layer of the epidermis, in addition to the nerve fibers and encapsulated corpuscles.²¹

Figure 37.4 (A) Rudimentary polydactyly. (B) There are many small nerves and some Meissner corpuscles in the upper dermis. (H&E)

Solitary circumscribed neuroma

Solitary circumscribed neuromas, also described as ‘palisaded and encapsulated neuromas’,¹¹ are uncommon, slow-growing painless nodules found usually on the face of middle-aged individuals.^{27,28} An extremely rare site of involvement is the penis.^{29,30} They average 0.5 cm in diameter. A patient with multiple cutaneous neuromas, but no other abnormality, has been reported.³¹ The patient reported as segmental neurofibromatosis of the face had lesions in which the published photomicrographs had some resemblance to a circumscribed neuroma.³² The morphological resemblance of solitary neuromas to traumatic neuromas has led to the suggestion that they represent a regenerative lesion in response to minor trauma to the site.^{17,33}

Histopathology¹¹

Solitary circumscribed neuroma usually presents as a single nodule confined to the dermis (Fig. 37.5). A multinodular or plexiform growth pattern is uncommon,³⁴ as is zosteriform palisaded encapsulated neuroma.³⁵ The neuroma is composed of well-developed fascicles separated by a loose matrix resembling the endoneurium of normal nerve (Fig. 37.6). Rarely, cells with an epithelioid appearance are present.³⁶ A thin perineural connective tissue capsule often surrounds the tumor, but there is no fibrous tissue sheath around fascicles, as seen in a traumatic neuroma.¹³ The perineural cells in the capsule contain epithelial membrane antigen.²⁷ The fascicles contain axons that stain positively for neurofilament,³⁷ and many are also myelinated;³⁸ they are S100 positive.^{39,40} Kossard and colleagues presented evidence challenging the concept that these tumors always contain axons.⁴¹ They found that some tumors lacked a significant axonal content, thus merging with the features of a schwannoma.⁴¹

The superficial part of a solitary neuroma is sometimes more loosely arranged, with a myxomatoid stroma, resembling a neurofibroma.¹¹ In one case, most of the lesion was myxoid, raising the possibility that the lesion was a nerve sheath myxoma with neuroma-like features.⁴² Prominent stromal vascularity has been reported.⁴³ Occasionally, a nerve can be traced into the lesion from below.

The overlying epidermis is usually normal or attenuated, but there is one report of overlying pseudoepitheliomatous hyperplasia.⁴⁴

Neuromas and the multiple endocrine neoplasia syndrome

Multiple mucosal neuromas may be the first manifestation^{45,46} of the multiple endocrine neoplasia syndrome (type 2b). This rare

autosomal dominant condition (OMIM 162300), which also includes medullary carcinoma of the thyroid, pheochromocytoma, and somatic abnormalities,^{47–51} is due to a mutation in the *RET* gene on chromosome 10q11.2. Multiple cutaneous neuromas, macular amyloidosis, and medullary carcinoma of the thyroid have been reported in a patient who was a heterozygote carrier of a mutation in the *RET* proto-oncogene.⁵² Multiple idiopathic mucosal and mucocutaneous neuromas have been reported in patients who had no features of MEN type 2b or other syndromes.^{53,54} Mucocutaneous neuromas have also been reported in association with germline mutations in the phosphatase and tensin homologue (*PTEN*) tumor suppressor gene on chromosome 10q23.31 (gene number 601728).⁵⁵ A spectrum of phenotypic expressions accompanies mutations in this gene, including Cowden’s syndrome,⁵⁶ Bannayan–Riley–Ruvalcaba syndrome (see p. 910), and some cases of Proteus-like syndrome.⁵⁵ They are all allelic.

Histopathology

Two different patterns may be seen.¹¹ The usual mucosal neuromas resemble solitary neuromas with haphazardly arranged bundles of

Figure 37.5 Solitary neuroma. A circumscribed dermal tumor is present. (H&E)

Figure 37.6 Solitary neuroma composed of nerve fascicles with no intervening collagen. (H&E)

Figure 37.7 Dermal hyperneury. (A) A large nerve fiber is present just above the mid dermis. (B) Another large nerve in the deep dermis. (H&E)

Schwann cell fascicles. In the other pattern, there are tortuous hyperplastic nerves with a thickened perineurium.¹¹

Hypertrophy of small nerves in the dermis ('dermal hyperneury') has also been noted in the clinically normal skin of patients with this syndrome.⁵⁷ Nerve hypertrophy has been reported in a patient with striated pigmentation and a marfanoid habitus, a possible forme fruste of this syndrome, but without the endocrine tumors.⁵⁸ Rarely, it may follow chronic irritation or rubbing of the skin (Fig. 37.7).⁵⁹

Ganglioneuroma

Ganglioneuromas may be found in the skin in patients with neuroblastomas and mature cutaneous secondary deposits and also in von Recklinghausen's disease where ganglion cells have been entrapped by a neurofibroma.⁶⁰ Primary cutaneous ganglioneuromas are exceedingly rare.^{61–64} Most cases develop after birth, but a congenital lesion has been reported.⁶⁵ They are clinically nondescript but histologically distinctive.⁶⁶

Histopathology

Ganglioneuromas consist of mature ganglion cells, which are usually intermixed with fascicles of spindle cells (Fig. 37.8).^{62,66} In one reported case, the ganglion cells were separate from the neuromatous elements.⁶⁷ The term 'ganglion cell choristoma' has been used for rare cases with ganglion cells and no stromal component.^{68,69} At the other

Figure 37.8 Ganglioneuroma. There is an admixture of ganglion cells – larger cells with irregular nuclear contours and generous amounts of cytoplasm – with smaller, compact spindle cells. The ganglion cells can be stained with antibodies to synaptophysin or microtubule-associated protein-2. (H&E) (Image courtesy Mark R. Wick, M.D.)

end of the spectrum is a case with abundant collagenous stroma containing scattered spindle and ganglion cells – a desmoplastic ganglioneuroma.⁷⁰ Overlying hyperkeratotic epidermal changes have been reported in two cases.⁷¹

The fusiform cells are strongly positive for S100 protein, but not the ganglion cells.⁷² In two recent reports, both the spindle cell component and the ganglion cells were positive for S100 protein and CD56.^{64,73} In one of these reports, they were also positive for neuron-specific enolase (NSE) and glial fibrillary acid protein (GFAP),⁶⁴ and in the other report they were positive for neurofilament protein.⁷³

EPITHELIAL SHEATH NEUROMA

Epithelial sheath neuroma is a rare tumor that presents as papules and nodules on the upper back of elderly patients.^{74,75} Lesions may be solitary.⁷⁵

Histopathology

The tumor is characterized by a proliferation of enlarged nerve fibers in the upper dermis ensheathed by squamous epithelium. The nerve fibers are much larger than normal for the dermis, and the perineural squamous epithelium is mature with focal cornification.⁷⁶ These structures are surrounded by delicate fibroplasia and a mild inflammatory cell infiltrate of lymphocytes with a few plasma cells.⁷⁷ There is a superficial resemblance to perineural invasion by a squamous cell carcinoma.

As expected, the nerves stain for a variety of neural markers, including S100 protein, and the epithelial sheaths for cytokeratins.⁷⁴ This entity differs from perineural invasion by the increased number and size of nerve fibers and by the lack of cytological atypia of the ensheathing cells.⁷⁸

RE-EXCISION PERINEURAL INVASION

Re-excision perineural invasion refers to the presence of mature squamous epithelium in the perineural spaces of normal cutaneous nerves

in re-excision specimens.^{79,80} It was originally described in the re-excision specimens of melanocytic lesions, but it has also been noted in re-excision specimens of other cutaneous tumors, when its distinction from perineural invasion can be more difficult. The perineural epithelium, however, is mature. It expresses MNF116 and other keratin markers. The epithelium is negative for S100 protein, melan-A, and HMB-45.⁷⁹ The origin of the epithelium is uncertain because no connection can be demonstrated with surface or adnexal epithelium.⁸¹ It may result from implantation during the initial procedure.⁷⁹ Other suggestions have been that this process may represent perineural squamous metaplasia,⁸² or an unusual reactive eccrine duct regenerative response to surgical injury, with growth into a perineural space.⁸³

PERINEURIOMA

Perineurioma is a rare tumor, composed exclusively of perineurial cells, that develops in the dermis, subcutis, or deep soft tissue.^{72,84,85} There are two main forms of perineurioma: a rare intraneural perineurioma involving named peripheral nerves⁸⁶ and a relatively more common extraneural variant that includes a conventional form, a sclerosing variant, a reticular (retiform) form,^{87,88} and a lipomatous variant,⁸⁹ which is a histological curiosity only. Another histological variant is the atypical, cellular form.⁹⁰ The malignant perineurioma is a variant of malignant peripheral nerve sheath tumor (MPNST).⁹¹ Less than 5% of MPNSTs express perineurial differentiation; sometimes this change is only focal.

The *conventional* form is found on the trunk and extremities of middle-aged adults. An association with neurofibromatosis type 1 (NF-1)⁹² and NF-2⁸⁴ has been reported only recently. Unfortunately, the term perineurioma was used in the past for localized hypertrophic neuropathy ('dermal hyperneury', discussed previously), with which it has no relationship at all.^{93,94}

Rare cases of a *granular perineurioma* have been reported.^{95,96} The lesion presented as a polypoid mass 4.5 cm in diameter in one case and as multiple lesions in another.⁹⁶

The *sclerosing perineurioma* is a distinctive variant with a predilection for the fingers and palms of young adults.^{97–102} This variant has been associated with aberrations of chromosome 10¹⁰³ and also with a cryptic deletion of the *NF2* gene at chromosome 22q12.2.^{86,98} This supports other evidence linking other types of perineurioma to this chromosome.^{104,105} Despite the allelic loss or mutation of the *NF2* gene in perineurioma, it is surprising that this tumor has only recently been described in association with NF-2.¹⁰⁶

Perineuriomas are firm, circumscribed nodules, usually 1.5–4 cm in diameter. Larger variants have been described, usually in the deep soft tissues.⁸⁴

Histopathology

The neoplasms are circumscribed non-encapsulated lesions composed of spindle cells with elongated, bipolar cytoplasmic processes.^{84,93} On low power, they usually resemble neurofibromas, with fascicles or individual cells oriented either parallel to each other or forming small concentric collections (Fig. 37.9).⁷² These concentric whorls ('onion bulbs') are an important clue to the diagnosis.¹⁰⁷ They sometimes have pacinian-like features.¹⁰⁵ Variants with granular cells and others with a plexiform or reticular pattern have been reported.^{87,108,109} The *reticular (retiform)* variant is composed of anastomosing cords of fusiform cells with bipolar cytoplasmic processes that wrap around islands of fibromyxoid stroma.⁸⁷ The stroma of the conventional type is also fibromyxoid; rarely, it contains calcospherites.⁹⁴ Myxoid features were prominent in one subungual perineurioma.¹¹⁰ Uncommonly, there is a fibrous or sclerotic stroma.¹¹¹ *Lipomatous perineurioma* refers to the presence of mature adipocytes admixed with spindle cells.⁸⁹

Figure 37.9 Perineurioma. (A) This is a paucicellular fibrous variant. Typical 'onion bulb' structures can be seen. (B) Another case. 'Onion bulbs' can be seen. (H&E)

The cases described by Mentzel and colleagues were more cellular lesions with a mixed lamellar and whorled pattern, sometimes with a marked storiform pattern. Focal stromal hyalinization and small aggregates of foam cells were present in some of their cases.⁹³ Such cases can be misdiagnosed as epithelioid histiocytomas.¹¹²

A cutaneous hybrid schwannoma–perineurioma has been described on a number of occasions.^{113–115} One example consisted of intermingled thin, tapered spindle cells (perineurial cells) and plump spindle cells (schwannian cells) that formed a monophasic-appearing tumor.¹¹³ The cells diffusely expressed S100 and epithelial membrane antigen (EMA), although CD34 apparently stained only perineurial cells.¹¹³ A plexiform hybrid tumor with features of perineurioma and neurothekeoma has been reported by Requena *et al.* The tumor showed positivity for S100A6, MiTF, NKI-C3, and EMA, and it showed focal, weaker staining for CD34, claudin-1, and Glut-1.¹¹⁶

The *epithelioid perineurioma* is composed of a syncytial-like proliferation of epithelioid cells with moderate amounts of eosinophilic cytoplasm. The cells in the reported case were positive for EMA and claudin-1.¹¹⁷

The *atypical cellular perineurioma* is a well-circumscribed lesion composed of spindle cells arranged in a storiform pattern.⁹⁰ Focally, it may appear laminated. The cytoplasm of the cells is eosinophilic and

well demarcated. The nuclei are elongated. Larger atypical cells are scattered through the tumor. A few cells have several nuclei. Mitoses are uncommon (1/20 high-power fields); atypical mitoses are not found.⁹⁰ In a lesion from the tongue, mitoses were conspicuous; psammoma bodies were also observed.¹¹⁸

Most of the tumor cells stain for EMA and vimentin.¹⁰⁰ Most cases show membranous positivity for claudin-1 protein,⁹¹ a tight junction-associated protein.¹¹⁹ In recent reports, cells have also expressed GLUT-1, protein gene product 9.5 (PGP 9.5), CD57,⁸⁶ vascular endothelial (VE)-cadherin,¹²⁰ and CD99.¹⁰² Focal positivity for factor XIIIa is often present.¹¹² The cells do not usually stain for S100 protein, CD34, chromogranin, or NSE,^{93,94} but Hornick and Fletcher reported a significant number of cases (64%) that expressed CD34.⁸⁵ Other CD34⁺ cases have been reported.¹²¹ In the variant with granular cells (discussed previously), these cells expressed S100 protein but not EMA, supporting their Schwann cell origin.¹⁰⁸

One of the reported *granular* perineuriomas expressed NK1/C3 but not S100 protein.⁹⁵

The *sclerosing perineurioma* is composed of abundant dense collagen and variable numbers of small, epithelioid, and spindled cells exhibiting corded, trabecular, and whorled (onion skin) patterns.⁹⁷ This tumor may be confused with the fibroma of tendon sheath, the sclerotic fibroma of Cowden's disease (see p. 974), and the pacinian collagenoma (see p. 975).¹²² A lipomatous variant of sclerosing perineurioma has been reported in the skin.¹²³ The cells stain for EMA and vimentin and often muscle-specific actin as well.⁹⁷ They also express GLUT-1, claudin-1, and collagen type IV.¹²³ The *fibrous perineurioma* is probably a less dense, more cellular, and better vascularized variant of the sclerosing perineurioma.¹¹¹

Intraneural perineuriomas cause fusiform expansion of a nerve, usually in the deep soft tissues. There are 'pseudo-onion bulbs' of concentrically arranged perineurial cells surrounding a central zone containing axons, Schwann cells, and fibrovascular stroma.⁹¹

Multiple hybrid granular cell tumors with admixed perineurioma elements were present in one patient.¹²⁴ Schwannoma-perineurioma hybrids also occur.^{125,126}

With fine needle aspiration cytology, a soft tissue perineurioma showed elongated spindle cells (and some stellate cells), singly and in clusters, with tapered ends, basophilic cytoplasm, and plump, round to oval nuclei with vesicular chromatin. Cells were arranged in whorls or palisades.¹²⁷

Electron microscopy

The spindle cells have lengthy, thin, bipolar cytoplasmic processes aligned in parallel and separated by small amounts of collagen.⁹¹ Similar features are seen in the epithelioid cells of the sclerosing variant.⁹¹ The cells contain few organelles, but pinocytotic vesicles are aligned along the plasmalemma of the cell processes.

Differential diagnosis

In contrast to sclerotic fibroma, the sclerotic perineurioma also features epithelioid and spindled cells in trabecular or whorled arrangements and are positive for EMA. Perineurioma can also resemble neurofibroma; like that tumor, it may assume a plexiform as well as a sclerotic configuration. However, other unique morphologies of perineurioma (e.g., concentric whorls or 'onion bulbs') and positive EMA and claudin-1 staining should allow its differentiation from neurofibroma. EMA positivity is also a key feature for differentiation of perineuriomas or hybrid lesions thereof from dermatofibrosarcoma protuberans, desmoplastic/spindle cell melanoma, or cellular digital fibroma.¹¹³ An angiofibroma-like perineurioma has been reported, its distinctive feature being perivascular cells that stained positively for EMA, claudin-1, and CD34.¹²⁸ Soft tissue perineurioma and meningioma can closely resemble one another, and EMA positivity is seen in both. A positive claudin-1⁺/Glut-1⁺ profile favors perineurioma,

whereas expression of somatostatin receptor 2 (SSTR2) and progesterone receptor (PR) favors meningioma.¹²⁹

SCHWANNOMA (NEURILEMMOMA)

Cutaneous schwannomas (neurilemmomas) are uncommon, slow-growing, usually solitary tumors with a propensity for the limbs of adults.¹³ They can also develop in the scalp, where their clinical features and encapsulation can resemble those of trichilemmal cyst.¹³⁰ Pain, tenderness, and paresthesias may be present in up to one-third of lesions.¹³¹⁻¹³⁴ They measure 2–4 cm in diameter.¹³ They are of Schwann cell origin.¹³⁵ Multiple tumors are uncommon and can occur in several clinical settings: in association with neurofibromas in von Recklinghausen's disease;¹³⁶ or as multiple, localized tumors that may be a distinct disease;^{137,138} in NF-2 (OMIM 101000), due to mutations in the *NF2* gene, located at 22q12.2, and characterized by vestibular schwannomas and other tumors; and in (familial) schwannomatosis (OMIM 162091), characterized by the development of multiple spinal, cranial, and peripheral schwannomas in the absence of a vestibular schwannoma.¹³⁹ Recently, mutations in the *IN11* gene, also known as *SMARCB1*, a tumor suppressor gene located in the immediate vicinity of *NF2*, have been implicated as the gene responsible for schwannomatosis.¹⁴⁰ This same gene had previously been implicated in the pathogenesis of malignant rhabdoid tumors of infancy.¹³⁹ A further gene, *CABIN1*, also near *NF2*, is thought to contribute to the formation of schwannomatosis, but further studies are needed to confirm whether it is co-located with either *NF2* or *IN11*.¹³⁹ It is hoped that these new findings will end the controversy in this area.¹⁴¹⁻¹⁴⁷

In addition to vestibular schwannomas, patients with NF-2 may also develop meningiomas and ependymomas. The *NF2* gene controls the synthesis of merlin, a protein found in the brain, nerves, eyes, and Schwann cells. Most gene mutations result in the production of a shortened version of merlin protein, which may then allow these cells to proliferate.¹⁴⁸ *Sporadic* schwannomas may also have *NF2* deletions.¹⁴⁸

Schwannomas also occur in the deep soft tissues, retroperitoneum, mediastinum, and tongue¹⁴⁹ and on the vestibulocochlear nerve. Local recurrence and malignant transformation are exceedingly rare.^{150,151}

The tumor is gray-white in color, encapsulated, with a smooth, glistening appearance.¹⁵² Cystic change is sometimes present, particularly in the larger, deeper tumors.

Histopathology¹³⁵

Schwannomas are circumscribed encapsulated tumors, usually confined to the subcutis. The nerve of origin may sometimes be seen along one border (Fig. 37.10). The agminate tumors and some of those in schwannomatosis are often situated in the dermis.¹³⁷ Multiple small tumor nodules may be present in these forms, as well as hypertrophied peripheral nerves.^{137,141} The term '*plexiform schwannoma*' has been applied to this type (Fig. 37.11).¹⁵³⁻¹⁵⁷ It originates from nerve sheath (see later).¹⁵⁸

Schwannomas are characteristically composed of two tissue types.¹³⁵ In the so-called 'Antoni A' areas, there are spindle-shaped Schwann cells arranged in interlacing fascicles. The cells have indistinct cytoplasmic borders. The nuclei may be aligned in rows or palisades, between which the cell processes are fused into eosinophilic masses forming Verocay bodies. A variant in which the Verocay bodies form 75–100% of the tumor has been described.¹⁵⁹ Conspicuous Verocay bodies were present in a schwannoma of the penis.¹⁶⁰ Antoni B tissue consists of a loose meshwork of gelatinous and microcystic tissue with widely separated Schwann cells. Lipid-laden macrophages, dilated blood vessels with thick hyaline walls, old and recent hemorrhage,

Figure 37.10 (A) Schwannoma. (B) There are Verocay bodies in the interlacing bundles of spindle-shaped cells (Antoni A tissue). (H&E)

lipofuscin, and sometimes calcified hyaline areas may also be present in Antoni B areas.^{2,135,161} 'Collagenous spherulosis' (radiating eosinophilic collagen fibers) has been reported in one case.¹⁶² Mast cells and non-specific cholinesterase may be demonstrated.¹³ Merkel cells are increased in the epidermis overlying schwannomas.¹⁶³

Figure 37.11 Plexiform schwannoma. The tumor bulges into the subcutis. There are multiple nodules. (H&E)

Immunoperoxidase methods demonstrate S100 protein,¹³⁷ vimentin,¹⁶⁴ SOX 10,¹⁶⁵ and myelin basic protein¹⁶⁶ in the tumor cells. GFAP is present in a small number of cases.^{164,167} EMA is found in the perineurial cells in the capsule of schwannomas, as in that of solitary neuromas (discussed previously).^{159,168} The conventional view has been that schwannomas, unlike neurofibromas, do not possess intratumoral axons. However, a recent study using an antibody to neurofilament protein found axons in 30–70% of schwannomas, with the incidence varying with the histological subtype.¹⁶⁹ All types of Schwann cell-derived tumors express the DNA-binding transcription factor, activating protein 2 (AP-2), mainly in their nucleus.¹⁷⁰

A cellular variant (*cellular schwannoma*), mostly found in the deeper tissues, has been described.^{171,172} There are compact spindle-shaped cells with mitoses and some storiform areas and also a near absence of Verocay bodies and Antoni B tissue.¹⁷¹ Rare variants with multiple glandular elements,¹⁷³ with pseudoglandular structures,¹⁷⁴ and with sweat duct differentiation¹⁷⁵ have been reported.

The *plexiform schwannoma* (discussed previously) has a superficial resemblance to the plexiform neurofibroma with multiple interlacing and interconnecting fascicles and nodules, composed predominantly of Antoni A-type tissue.¹⁵⁸ Most tumors occur in the dermis and subcutis. A deep-seated variant has also been described.¹⁷⁶ In comparison with the superficial variety, the deep variant has a predilection for females, can occur in a congenital setting, and can show necrosis and myxoid change.¹⁷⁶ A further subset of plexiform schwannomas occurs in a congenital or childhood setting. It was previously considered a form of MPNST.¹⁷⁷ Despite their cellular pleomorphism, they are now known to have a benign behavior.

A *neuroblastoma-like variant*, with large rosette-like structures and fibrillary collagenous centers, has been described.^{178,179} The presence of intervening Antoni B areas and an absence of necrosis or mitoses assist in making a diagnosis. One case presented with anetoderma-like features.¹⁸⁰ The cells express S100 protein, but not neuron-specific enolase, as occurs in the smaller rosettes of neuroblastoma.¹⁸¹ Only one of the several cases tested expressed GFAP.¹⁷⁹

The *epithelioid schwannoma* is an extremely rare variant composed largely of epithelioid cells, in which there is a lack of mitotic activity.^{182–185} In a study of 33 cases of benign epithelioid peripheral nerve sheath tumors (BEPNSTs), 18 were subclassified as epithelioid

neurofibromas and 15 as epithelioid schwannoma, although in 5 of these cases the absence of nuclear palisading, the presence of uniform cellularity, and the presence of a significant CD34⁺ spindle cell population led to their classification as BEPNSTs of indeterminate histogenesis.¹⁸⁵ A collagen-rich variant of BEPNST has since been reported.¹⁸⁶ Features of classic schwannoma are usually present in some areas of the tumor.¹⁸³ There is a thin capsule containing EMA⁺ cells, although this was not present in a subsequent case.¹⁸⁷ Type IV collagen encircles individual cells within the tumor.¹⁸² The cells stain for S100 protein but not HMB-45, and they have a low proliferation index as judged by Ki-67 staining.¹⁸⁸ An epithelioid schwannoma that was also plexiform has been reported.¹⁸⁹

The *pseudoglandular schwannoma* is an extremely rare variant composed of gland-like spaces containing mucinous material and lined by Schwann cells that are strongly positive for S100 protein, type IV collagen, and GFAP and are negative for EMA and cytokeratins AE1/AE3.^{190–192} In one study of schwannomas in multiple anatomic sites, pseudoglandular changes were found in almost 8% of cases.¹⁹¹ In another case, the glandular cells stained with CAM5.2 and EMA, but not for S100 protein.¹⁹³ This may be a true glandular variant. This variant is more common in schwannomas of the central nervous system.¹⁹¹

Another type of schwannoma is the *psammomatous melanotic schwannoma*, which contains melanin and scattered psammoma bodies (see later).

The *Wagner–Meissner schwannoma* has a monomorphous morphology with sheets of corpuscles having a lamellar structure.¹⁹⁴ The nuclei are predominantly located at the periphery of the corpuscle.¹⁹⁴ They are separated by thin fibrous strands. There are some similarities to a perineurioma in the published photomicrographs.

The term '*congenital neural hamartoma (fascicular schwannoma)*' has been used for an unencapsulated dermal tumor composed of fascicles of Schwann cells with frequent Verocay body-like structures.¹⁹⁵ Unlike cutaneous neuromas, there are no axons present.

The *ancient schwannoma* demonstrates enlarged, hyperchromatic, and otherwise bizarre nuclei, and it is usually found in traumatized, superficial lesions of long duration (Fig. 37.12). Some studies have shown that ancient changes are actually common in benign cutaneous schwannomas, with vascular anomalies that may be related to degenerative changes.¹⁶¹ A few mitotic figures can be found in these lesions without necessarily implying malignancy. In fact, malignant change in a schwannoma is particularly rare,¹⁵⁰ generally restricted to large and deep-seated lesions.

Electron microscopy

There are aggregates of mature Schwann cells with thin, complexly entangled cytoplasmic processes but only rare cell junctions.^{2,196} One report suggested that the Antoni B areas showed features of degeneration,¹⁹⁷ but this finding has not been confirmed by others.¹⁸

Differential diagnosis

Leiomyomas can demonstrate variation in cell density and nuclear palisading that mimics schwannoma, but those tumors are immunoreactive for smooth muscle markers such as actin, desmin, caldesmon, and calponin and are only occasionally S100 positive. So-called 'neuroid' basal cell carcinomas also feature prominent nuclear palisading, but they are positive for cytokeratins and negative for neural markers.¹⁹⁸ The presence within schwannomas of small ovoid cells surrounding fibrillary material (resembling neuropil) is the hallmark of the neuroblastoma-like variant. However, unlike metastatic neuroblastoma, neuroblastoma-like schwannoma is strongly, diffusely positive for S100 and vimentin, and it lacks affinity for synaptophysin and NB84, an antibody raised against an antigen from human neuroblastoma tissue that recognizes a 57-kDa molecule.¹⁹⁹

Figure 37.12 Ancient schwannoma. (A) There are nuclear pleomorphism and hyperchromasia in this example of an ancient schwannoma. (B) Detail of the nuclear changes in this lesion. Mitotic figures were difficult to identify in this example. (H&E)

PSAMMOMATOUS MELANOTIC SCHWANNOMA

The rare psammomatous melanotic schwannoma is an unusual component of Carney's complex (myxomas, spotty pigmentation, and endocrinopathy).^{200,201} The most common locations are the posterior spinal nerve roots, gastrointestinal tract, bone, and soft tissue;²⁰² the skin is an uncommon site.²⁰³ Multiple lesions may be present.²⁰⁰

Histopathology

This tumor is usually well circumscribed but only partly encapsulated. There is a mixture of polygonal and fusiform cells, many of which are heavily pigmented melanocytes (Fig. 37.13).⁷² Psammoma bodies are present in varying numbers. Sometimes they coalesce to form larger, irregular masses. Adipocytes are often present.

The tumor cells stain positively for S100 protein, HMB-45, MART-1, synaptophysin, and vimentin.²⁰⁴

Figure 37.13 Melanotic schwannoma. Densely pigmented cytoplasm is evident. Psammoma bodies are not present in this example. (H&E) (Image courtesy Mark R. Wick, M.D.)

Cytology smears have shown cells, loosely organized and in sheets, that were epithelioid and spindled, with oval to elongated nuclei, small nucleoli, and dark brown to black cytoplasmic pigment; psammoma bodies could also be identified.²⁰⁵

A **malignant melanotic schwannoma** has been reported.²⁰⁶ It did not occur in the setting of Carney's complex, nor were there psammoma bodies. Epithelioid cells with melanin were seen in the primary lesion, whereas spindle cells dominated in the recurrence.²⁰⁶

NEUROFIBROMA AND NEUROFIBROMATOSIS

Neurofibromas may occur as a solitary tumor or as multiple lesions in a segmental or widespread distribution, referred to as neurofibromatosis. The histopathology of the neurofibromas in these different clinical settings is similar and is considered together.

Solitary neurofibromas are papular, nodular, or pedunculated tumors with a predilection for the upper trunk.¹³ Rarely, they have a diffuse pattern.²⁰⁷ They are soft and tend to invaginate on pressure (the 'buttonhole' sign). Subungual lesions have been reported;^{208,209} in another case, a toe was involved.²¹⁰

Neurofibromatosis, described by von Recklinghausen in 1882, is a clinically heterogeneous disorder with varied manifestations affecting the skin, soft tissues, blood vessels, and the peripheral and central nervous systems.^{211,212} It is said to affect 80,000 individuals in the United States.²¹³ It has a significant impact on quality of life.²¹⁴ Riccardi proposed eight clinical subtypes of neurofibromatosis (NF-1 to NF-8).²¹⁵ NF-1 is classic von Recklinghausen's disease, which accounts for 85–90% of all cases. NF-2 is associated with vestibular neuromas and sometimes other intracranial tumors. It was discussed previously. Cutaneous tumors, particularly schwannomas, are found in more than 50% of cases.²¹⁶ The inheritance of NF-2 is autosomal dominant, with the gene being located on chromosome 22q12.2. NF-3 is a mixed form combining features of NF-1 and NF-2. NF-4 is a variant form with diffuse neurofibromas and café-au-lait pigmentation but without many of the other clinical features that typify NF-1. NF-5 is the segmental form. NF-6 has prominent café-au-lait pigmentation as the sole manifestation. NF-7 is a late-onset type, and NF-8 is a miscellaneous group not categorized into the other subtypes.^{215,217}

Prenatal diagnosis of neurofibromatosis has not been routinely available because of the large size of the gene. Furthermore, the high rate of new mutations (approximately 50% of all cases) means that the index of suspicion that a fetus may be affected is consequently lowered.²¹⁸ In recent years, prenatal screening has become more effective.²¹⁹ Both prenatal and preimplantation genetic diagnosis can be used for individuals with NF-1.²²⁰

Classic neurofibromatosis (NF-1)

NF-1 (OMIM 162200) is inherited as an autosomal dominant trait, although spontaneous (new) mutations account for up to 50% of all NF-1 probands.^{218,221} Its prevalence is approximately 1 in 3000–4000 individuals worldwide.²¹⁹ It is linked to the *NF1* gene located on the long arm of chromosome 17 (17q11.2).²²² Specific mutations of the *NF1* gene may be related to the expression of a specific phenotype.²²³ Neurofibromin is the protein encoded by the gene, which appears to have a tumor suppressor function. It is capable of downregulation of the p21-ras oncogene, and it negatively regulates mitogen-activated protein kinase (MAPK) signaling.²²⁴ Recently, a germline loss of function in the *SPRED1* gene on chromosome 15 has been reported that resulted in an NF-1-like phenotype.²²⁴ Several phenotypically overlapping syndromes (Noonan syndrome, LEOPARD syndrome, Costello syndrome, and cardio-facio-cutaneous syndrome) all result from mutations in genes encoding key components of the RAS-MAPK pathway.²²⁴ Other signaling pathways, such as hedgehog one, may be involved in tumorigenesis in NF-1.²²⁵

Café-au-lait pigmentation, which varies from small macular areas to large patches of pigmentation, is present in 99% of cases.²¹³ The pigmentation is present at birth or appears early in childhood before other stigmata of the disease.²²⁶ It may be found in other conditions,²²⁷ but the presence of six or more patches is said to be diagnostic of neurofibromatosis.²²⁸ A giant garment-like café-au-lait macule, involving the lower half of the trunk, has been reported in a patient with NF-1. It was regarded as a possible type 2 segmental manifestation of the disease.²²⁹ Axillary freckling is present in approximately 20% of patients. Small lentiginous melanocytic nevi are increased in number.²³⁰

The neurofibromas are multiple and sometimes disfiguring. They appear before puberty, although late onset has been recorded.^{231,232} Congenital, disseminated disease is extremely rare.²³³ Sex incidence has been equal in many studies. The location of the neurofibromas has been variable, with the extremities the predominant site in one African series.²³² Neurofibromas may develop for the first time in pregnancy; women who already have tumors may experience an increase in the size and number of the lesions during pregnancy.²³⁴ The screening of school-aged children for neurofibromatosis is controversial.^{235,236} Plexiform neurofibromas,¹³ which were thought to be pathognomonic of neurofibromatosis, may rarely present as solitary lesions without any features of neurofibromatosis.²³⁷ They may present as large deep tumors or localized areas of deformity.^{238,239} They are found in approximately 25% of cases.^{228,240} In approximately 10% of cases, plexiform neurofibromas are multiple.²⁴¹ Schwannomas are sometimes present as well.

Other clinical features of the classic form are pigmented hamartomas of the iris (Lisch nodules),^{242–244} poliosis circumscripta,²⁴⁵ macrocephaly, learning disability, kyphoscoliosis, bone hypertrophy, pseudoarthrosis, and vascular lesions.^{242,246–249} Shortened maxilla, mandible, and cranial base have been found in NF-1 patients compared to normal controls; the results were statistically significant among adults.²⁵⁰ Somatic mutations may explain the variable expressivity of the *NF1* phenotype.²⁵¹ The classic form has been reported in a patient with tuberous sclerosis²⁵² and in one with the McCune–Albright syndrome.²⁵³ The association with mycosis fungoides was probably fortuitous.²⁵⁴ Elephantiasis neuromatosa, with localized gigantism or thick redundant folds of skin, is rare.^{246,255} Neurofibromas, each with a halo of

depigmentation, have been reported in one patient with presumptive mild neurofibromatosis.²⁵⁶ Generalized vitiligo was present in another case in which the neurofibromas showed the halo phenomenon.²⁵⁷ Another rare association is hypertrophy of pacinian corpuscles.²⁵⁸

Malignant degeneration of neurofibromas occurs in 2 or 3% of patients,²²⁸ although higher percentages have been reported in some series.²⁴⁰ Pain, neurological deficit, and tumor enlargement are features suspicious for malignant transformation.²⁵⁹ In a study of cutaneous lesions of patients with NF1, cathepsin K – a cysteine protease with collagenolytic and elastolytic properties – was found to be expressed in all cutaneous MPNSTs but not in neurofibromas or in the neurofibroma areas surrounding MPNST areas.²⁶⁰ SOX 9 is a transcription factor linked to hedgehog pathways. Expression of SOX 9, although not unique to MPNST among spindle cell sarcomas, has been found to be upregulated in MPNST compared to neurofibromas at the protein level, and in MPNST and plexiform neurofibromas compared to diffuse neurofibromas at the mRNA level.²⁶¹ In addition, various other sarcomas,²⁶² melanomas,^{240,263,264} and visceral carcinomas²⁴⁰ have been reported, although the latter may not be increased in incidence.²⁶⁵ Clinical follow-up seems to be as effective as imaging studies in detecting these complications.²⁶⁶ Subcutaneous neurofibromas and the absence of cutaneous lesions are two independent risk factors for mortality in patients with NF-1.²⁶⁷ A study of NF-1 patients referred to the National French Referral Center for Neurofibromatosis found excess mortality in this group compared to the general population; the cause of death was MPNST in 60% of patients for whom this information was available.²⁶⁸

Segmental neurofibromatosis (NF-5)

The segmental variant (NF-5) is a heterogeneous group.^{269–277} Café-au-lait pigmentation is present in some cases;^{238,278–281} there are usually no other stigmata of neurofibromatosis (other than neurofibromas) and no family history.^{282–285} This localized form may be due to mosaicism resulting from a postzygotic *NF1* gene mutation.^{286,287} There is a tendency now to disregard the Riccardi classification and to refer to 'mosaic NF1' for all cases resulting from a postzygotic *NF1* lesion.²⁸⁸ Such inactivations may result in generalized mild disease, segmental disease, or gonadal mosaicism.²⁸⁸ Determining when, and in what cell types, inactivation of the *NF1* gene occurs is critical for understanding the various clinical manifestations of mosaic or segmental NF1.²⁸⁸ Variants of the segmental form include a localized,²⁸⁹ a unilateral,^{269,283} and a bilateral^{269,287,290–293} segmental form; a form associated with deep neural tumors;²⁹⁴ and a rare hereditary form.²⁹⁵ Most cases involve the trunk; the face is uncommonly involved.²⁹⁶ More than 100 cases of NF-5 have been reported. An association with an internal malignancy is very rare.²⁸⁷ The simultaneous occurrence of NF-5 and clustered incomplete tuberous sclerosis has been reported.²⁹⁷ Multiple glomus tumors have been reported in association with segmental neurofibromatosis.²⁹⁸ Malignancies occur in patients with segmental neurofibromatosis, most often malignant peripheral nerve sheath tumor and malignant melanoma.²⁹⁹

Neurofibromatosis localized to the vulva and perianal area can be classified with this group.^{300,301}

Histopathology

Cutaneous neurofibromas are non-encapsulated, loosely textured tumors centered on the dermis.^{13,302} There is often extension into the subcutis, sometimes in a diffuse infiltrative pattern.³⁰² An overlying grenz zone separates the lesion from the undersurface of the epidermis. The lesion is composed of delicate fascicles, usually only a single cell thick.¹¹ The cells have an oval or spindle-shaped nucleus and scant, indefinite cytoplasm (Fig. 37.14). Vacuolated cells are found focally in a small number of tumors.³⁰³ Floret-like multinucleated giant cells

Figure 37.14 (A) Neurofibroma composed of thin fascicles of cells, each with a 'wavy', spindle-shaped nucleus. (H&E) **(B)** Higher power view showing spindle cells, some with 'buckled' or 'S-shaped' nuclei. Several mast cells are also identified. (H&E)

were present in a neurofibroma arising in a patient with NF-1.³⁰⁴ There is sometimes nuclear pleomorphism, but mitoses are rare. Neurofibromas with high cellularity and atypia have been called dysplastic neurofibromas. Patients with such lesions require increased surveillance because of a potential risk for malignant transformation.³⁰⁵ The matrix is pale staining with delicate wavy collagen; rarely, the matrix is rich in mucin or is sclerosing or hyalinized.^{209,302,306} Solitary neurofibromas are sometimes more compact than those in neurofibromatosis.¹³⁵ Blood vessels are increased in number in the stroma.³⁰⁷ A Bodian stain will demonstrate some axonal material but not in the 1:1 ratio with Schwann cells, as occurs in neuromas.¹¹ Mast cells,³⁰⁸ nonspecific cholinesterase,²⁸⁵ S100 protein, myelin basic protein,¹⁶⁶ and factor XIIIa^{309,310} can be demonstrated by the appropriate techniques. Mast cells are more numerous and more evenly distributed in diffuse neurofibromas than in encapsulated neurofibromas, whereas they tend to be distributed in the periphery of encapsulated neurofibromas.³¹¹ Podoplanin expression, using the D2-40 antibody, is found in a small number of neurofibromas. It is found more often in neurilemmomas.³¹² Podoplanin expression has been seen in the compact portions of schwannoma and 'atypical' neurofibromas (defined as lesions showing

Figure 37.15 Plexiform neurofibroma. There is cylindrical enlargement of a subcutaneous nerve. Large nerve fascicles are embedded in a cellular matrix, confined within the epineurium of the nerve. (H&E)

‘regressive’ changes – nuclear atypia, nests of foam cells, and vascular fibrosis). It is also seen in the invasive front of MPNST, but the finding of podoplanin in atypical neurofibromas is not associated with progression to MPNST in those lesions.³¹³ According to the authors of this study, CD34 is of limited value in classification and grading of peripheral nerve sheath tumors because of its ubiquitous expression.³¹³ The mast cells may not always be quiescent as evidenced by the report of abundant eosinophils in a solitary neurofibroma.³¹⁴

Various growth factors and their receptors are also present.³¹⁵ Neural cell adhesion molecule (NCAM–CD56) was present in one study in 100% of schwannomas and MPNSTs, 86% of neurofibromas, 76% of neurotized nevi, but only 50% of desmoplastic/spindle cell melanomas.³¹⁶ The staining was less intense in the melanomas than in the neural tumors.³¹⁶

Plexiform neurofibromas are a distinct variant in which there is irregular cylindrical or fusiform enlargement of a subcutaneous or deep nerve;¹³ rarely, they arise in the dermis.³¹⁷ Numerous large nerve fascicles are embedded in a cellular matrix containing abundant mucin as well as collagen, fibroblasts, and Schwann cells (Fig. 37.15).¹¹ Initially, this proliferation of nerve fibers is confined within the epineurium of the involved nerve.¹¹ The massive soft tissue neurofibroma is highly specific for NF-1. It is worrisome because its size may mask the development of a malignant peripheral nerve sheath tumor.³¹⁸

The *pigmented plexiform neurofibroma* is a subset of plexiform neurofibromas with hyperpigmentation and hypertrichosis of the overlying skin.³¹⁹ There is melanocytic hyperplasia at the dermoepidermal junction and single pigmented melanocytes with occasional small nests in the papillary dermis and scattered within the underlying neurofibromatous tissue.³¹⁹ Immunohistochemical staining with melan-A (MART-1) confirms the melanocytic differentiation of these scattered nests and individual cells, whereas GFAP and Leu-7 are detected only within plexiform areas and neuroid spindle cells.³¹⁹ The case reported as a **cutaneous melanocytoneuroma** had an intraneural proliferation of large epithelioid cells with eosinophilic cytoplasm with prominent cell borders, imparting a plant-like pattern.³²⁰ Involvement of smaller nerve twigs gave the lesion a plexiform appearance. The cells expressed S100 protein, melan-A, HMB-45, microphthalmia-associated transcription factor (MITF), and PGP9.5.³²⁰ The lesion was surrounded by an EMA⁺ perineurial layer.³²⁰

Other findings in neurofibromatosis are schwannomas (neurilemmomas), tumors with features of both neurofibroma and schwannoma (hybrid lesions),^{321,322} and neurofibromas containing scattered, possibly entrapped, ganglion cells. Pilar dysplasia and folliculosebaceous proliferations have been reported overlying neurofibromas.^{323,324} Vascular changes are rarely found.³²⁵ They include smooth muscle islands in the intima of vessels.²⁴⁷ Fibromuscular dysplasia of larger cutaneous vessels was so extensive in one case that it resulted in cutaneous ulceration.³²⁶ If random biopsies are taken from apparently normal skin in patients with NF-1, microscopic (occult) neurofibromas are sometimes found. Abundant S100⁺ cells may also be found within the perifollicular fibrous tissue.^{327,328} In elephantiasis neuromatosa, there is a diffuse proliferation of Schwann cells and axons in the subcutis.¹³⁵ Islands of cartilage are present, rarely, in this tissue.¹³⁵ Glandular epithelial structures (*epithelioid neurofibroma*) have been reported in the stroma.^{185,273,329}

In a review of the histopathological variants of neurofibroma, Megahed listed 10 variants:³⁰² classic, cellular, myxoid, hyalinized, epithelioid, plexiform, diffuse, pigmented, granular cell, and pacinian. Some of these variants are regarded by others as discrete entities, whereas others represent morphological curiosities.

An additional variant is the comparatively recently described *dendritic cell neurofibroma with pseudorosettes*.^{330,331} Its development within the confines of the perineurium in the skin in one case supports its origin as a peripheral nerve sheath tumor and not a melanocytic nevus as was thought for a brief period.³³² It does not appear to be associated with NF-1 or NF-2.³³³ The dermis is filled with tumor nodules that are oval shaped and oriented more or less vertically. Two types of cells are present: type I cells are small, dark, lymphocyte-like cells with inconspicuous cytoplasm, and type II cells are larger, with pale-staining vesicular nuclei and abundant pale eosinophilic cytoplasm.³³² Type I cells are arranged concentrically around type II cells, forming pseudorosettes. Both cell types express S100 protein and CD57, and varying proportions of both cell types express CD56 and PGP9.5.³³²

The *sclerotic neurofibroma* is an extremely rare variant in which there are scant cells and thick collagen bundles arranged chiefly in an interweaving pattern with prominent clefts.^{334,335} The tumor cells have uniform fusiform nuclei. There are some similarities to sclerotic fibroma.³³⁶

The rare *pigmented neurofibroma*, six cases of which were described by Bird and Willis in 1969,³³⁷ had received scant attention until a report of 19 cases.³³⁸ It is composed of whorled fibrillar ovoid structures resembling Wagner–Meissner bodies (Fig. 37.16).^{338,339} Melanin is present in macrophages and in some of the tumor cells, which stain for S100 protein, HMB-45, and melan-A. In the few cases tested, the cells also expressed CD34.³³⁸ There is also co-expression of *MET* proto-oncogene and MITF.³⁴⁰ In addition, a neurofibroma has been described that contained nonpigmented epithelioid cells that proved to be melanocytes. Although the entire tumor was S100⁺, the epithelioid cells stained positively for MART-1, HMB-45, and MITF.³⁴¹ These lesions represent two of four categories of lesions combining melanocytes and neural cells: (1) pigmented neural tumors containing melanocytes, including the pigmented neurofibroma as well as pigmented melanotic schwannoma, both psammomatous (discussed previously) and nonpsammomatous; and (2) nonpigmented neural tumors with melanocytic differentiation, including the nonpigmented neurofibroma containing nonpigmented epithelioid melanocytes as well as the melanocytoneuroma and melanocytic schwannoma.³⁴¹ The other two categories are (3) collision lesions, such as a neurofibroma occurring adjacent to a melanocytic nevus, and (4) melanocytic tumors with neural morphology, including neurotized melanocytic nevi, perineuriomatous melanocytic nevi, and melanomas with neural features.³⁴¹

The *cellular neurofibroma* can be difficult to distinguish from an MPNST, particularly if atypia and low-grade mitotic activity are present. It has been suggested that ancillary studies (p53 expression,

Figure 37.16 Pigmented neurofibroma. Melanin is abundant in this lesion, which displays whorled, ovoid structures bearing a resemblance to Wagner–Meissner bodies. (H&E)

Ki-67 immunostaining, and flow cytometry to assess DNA content) may be useful in confirming a benign diagnosis in these cases.³⁴² Further studies are needed to confirm these findings.³⁴³

The *lipomatous neurofibroma* is a recently described variant of neurofibroma characterized by the presence of intratumoral fat.^{344–346} In one study of 320 cases of neurofibroma, fat was observed in 22 (6.9%).³⁴⁷ It was focal in 18 of these cases, whereas in the other 4 it was diffuse with mature adipocytes regularly interspersed with the spindle cells of the neurofibroma.³⁴⁷

Giant pigment granules (macromelanosomes) are often present in melanocytes and basal keratinocytes in the *café-au-lait spots* of neurofibromatosis.³⁴⁸ The granules can just be seen with the light microscope. They are probably increased in older individuals.³⁴⁹ Macromelanosomes are not present in all cases of neurofibromatosis; their presence is not pathognomonic because they can also be found in several other conditions.^{348,350}

Electron microscopy

Neurofibromas are composed of fusiform or stellate cells that are widely separated by individual collagen bundles and matrix.^{19,196} They have usually been interpreted as Schwann cells,¹⁹ but one report claimed that the principal cell is the perineurial cell, although scattered Schwann cell–axon complexes are also present.²

Differential diagnosis

Neurofibromas can closely resemble neurotized melanocytic intradermal nevi, including amelanotic ‘blue’ nevi and Spitz nevi. Serial sections searching for small foci of obvious melanocytes (e.g., in nested arrangements) may be necessary. Most neurofibromas and neurotized nevi are S100⁺, but within that differential diagnosis, only neurofibromas express factor XIIIa. Another problem can be created by the CD34 positivity of neurofibromas, particularly in the occasional lesion that fails to stain for S100 protein, CD56, or CD57. Dendritic neurofibromas with pseudorosettes can be confused with primitive neuroectodermal tumor/extraskeletal Ewing’s sarcoma, but the former contains zones of spindle cell growth and fails to express CD99 – features not seen in primitive neuroectodermal tumor. Perineuriomas can have plexiform or sclerotic features, resembling neurofibromas, but the former can be recognized by its tendency to form parallel or concentric arrangements of spindle cells and its staining for epithelial

Figure 37.17 Pacinioma composed of enlarged Vater–Pacini corpuscles. (H&E)

membrane antigen and claudin-1. There has been controversy about the coexistence of NF-1 and piebaldism in that some patients with the latter have axillary freckling and six or more café-au-lait macules, meeting criteria for NF-1.³⁵¹ In a recent study of a family with piebaldism, two members of which met diagnostic criteria for NF-1, a novel complex mutation in the *KIT* gene was found in several family members, but the proband, who met criteria for NF-1, had no detectable mutations in *NF1* or *SPRED1* genes. This suggests that piebaldism may indeed be confused with NF-1, and molecular testing may be necessary for distinction between the two.³⁵²

PACINIOMA AND PACINIAN NEUROFIBROMA

The term ‘pacinioma’ has been applied to the rare finding of a hamartomatous overgrowth of mature Vater–Pacini corpuscles (Fig. 37.17).^{353,354} Another term used is ‘hyperplasia and hypertrophy of pacinian corpuscles’.³⁵⁵ Bale reported two such lesions in the sacral region associated with spina bifida occulta.³⁵³ Pain and local tenderness are often present.³⁵⁶ Sometimes a history of prior trauma to the site can be elicited.³⁵⁵ An association with neurofibromatosis (NF-1) is extremely rare.²⁵⁸

Pacinian neurofibroma (pacinian neuroma) is a rare tumor of the digits, hands, and feet. It is composed of round or ovoid corpuscles with multiple concentric lamellae.^{357–359} They do not have the perfect structure of a Vater–Pacini corpuscle, but the resemblance is close. The report of a case with multiple hairy lesions on the buttock composed of rudimentary Vater–Pacini corpuscles suggests that the distinction between the hamartomatous pacinioma and the pacinian neurofibroma is artificial.³⁶⁰ In another case, multiple tiny lesions were present on the ring finger in one patient, associated with marked vascular changes of the glomus type of arteriovenous anastomoses.³⁶¹ Some of the cases reported in the literature as pacinian neurofibromas would now be reclassified as nerve sheath myxomas.³⁶² These latter tumors have less resemblance to Vater–Pacini corpuscles and they contain more stromal mucin than true pacinian neurofibromas.

NERVE SHEATH MYXOMA

The nerve sheath myxoma has been a controversial entity for many years,³⁶³ particularly since the description in 1980 of the neurothekeoma by Gallagher and Helwig.³⁶⁴ For many years, nerve sheath myxoma and neurothekeoma were regarded as neural tumors at either end of a histological spectrum.^{365–368} A 2005 study of a large series of tumors coded at the Armed Forces Institute of Pathology (AFIP) as a nerve sheath myxoma or neurothekeoma resulted in 57 cases of nerve sheath myxoma being reviewed.³⁶⁹ The authors concluded that this tumor was unrelated to so-called cellular and mixed-type neurothekeoma.³⁶⁹

Nerve sheath myxomas are rare tumors that occur at all ages, but the peak incidence is in the fourth decade of life. There is a predilection for the extremities, particularly the hands,³⁷⁰ and the knee/pretibial region.³⁶⁹ The tumors are solitary, slow-growing multinodular masses. They are usually painless. Tumor size varies from 0.5 to 2.5 cm in diameter. Recurrences are common after simple excision, particularly if the lesion is incompletely removed.³⁶⁹

This lesion is a peripheral nerve sheath tumor of Schwann cell origin, as shown by its highly reproducible immunohistochemical findings (see later).^{369,371}

Histopathology^{369,372-374}

The nerve sheath myxoma is multilobulated and non-encapsulated (Fig. 37.18). It is centered on the reticular dermis but often extends into the superficial subcutis.³⁷⁴ The lobules are composed of spindle-shaped, stellate, and sometimes epithelioid cells arranged in a swirling, lamellar, and often concentric pattern. Syncytial-like aggregates are also present. Vacuolated cells are often seen. The cellular elements are embedded in a myxoid stroma, which is usually abundant in those tumors in which stellate and bipolar cells predominate. Chondroitin-4 or chondroitin-6 sulfate is the principal heteroglycan present.^{363,373} There is a peripheral fibrous border. There is variable nuclear hyperchromatism and sometimes nuclear atypia. Mitoses are uncommon. In one case, melanin was present in some tumor cells.³⁷¹

The cells are immunoreactive for S100 protein, GFAP, NSE, and CD57.^{369,375-377} They are bordered by collagen IV. Perineurial cells expressing EMA are present in small numbers, primarily in the fibrous tissue directly adjacent to the myxoid nodules.³⁶⁹ Both nerve sheath myxoma and neurothekeoma express S100A6.³⁷⁸

NEUROTHEKEOMA

Neurothekeomas (cellular neurothekeomas) are distinctive cutaneous tumors of uncertain histogenesis.^{379,380} Because some lesions have a myxoid stroma, they were regarded for many years as part of a histological spectrum that included nerve sheath myxoma. However, there is no good evidence that they even show nerve sheath differentiation.³⁷⁹ Until this is clarified, this benign tumor will be considered in this section.

Neurothekeomas are found mostly on the face and upper extremities.³⁷⁹⁻³⁸² They are not associated with neurofibromatosis. There is a predilection for females³⁸³ and for young adults; cases in children are well documented.^{383,384} They present as asymptomatic, dome-shaped nodules that measure 0.3–6 cm or more in diameter.^{385,386} The mean tumor size in one series was 1.1 cm.³⁷⁹ Neurothekeomas are usually solitary, but multiple lesions were present in two cases,^{380,387} and agminated cellular neurothekeomas have also been reported.³⁸⁸ Uncommonly, they recur if inadequately or marginally excised.

The histogenesis of these tumors is controversial.³⁸⁹ The finding of PG-M1, a reliable marker for histiocytic differentiation, in one case led to speculation that the tumor was of fibrohistiocytic lineage.³⁹⁰ Hornick and Fletcher concluded that there is no compelling evidence for a neuroectodermal derivation.³⁷⁹ Another study postulated an origin from fibroblastic cells with the ability to differentiate into myofibroblasts and a tendency to recruit histiocytic cells.³⁸⁰

Histopathology

Although neurothekeoma is usually a dermal tumor, subcutaneous extension and/or skeletal muscle involvement may occur.^{379,391} It is composed of nests and fascicles, giving a multilobular appearance (Fig. 37.19). The intervening stroma may be hyalinized; often there are myxoid foci.³⁹² The nests of spindle cells sometimes have a concentric or whorling arrangement. A plexiform pattern may sometimes be

Figure 37.18 Nerve sheath myxoma. (A) Spindle-shaped cells are arranged in a swirling and concentric manner. The stroma is myxoid. (H&E) (B) This example shows the multilobulated configuration and abundant, myxoid stroma. (H&E)

Figure 37.19 (A) Neurothekeoma. (B) Tumor fascicles merge with the intervening dermal collagen. (H&E)

Figure 37.20 (A) Neurothekeoma. (B) This is a further case with both epithelioid and spindle cells and some nuclear atypia. (H&E)

present,³⁹³ as may a fascicular configuration resembling dermatofibroma.³⁹⁴ Perineural involvement, with tumor cells surrounding dermal nerves, has also been reported.³⁹⁵ In a study of 37 cases by Stratton and Billings, the key diagnostic feature appeared to be the nests of epithelioid to spindled cells, even in situations in which this change was only focal. Other cellular configurations were fascicular, sheet-like, and corded. Cytologic atypia was noted, including a few cases with severe atypia, and the mean mitotic rate was 2 mm².³⁹⁶ These authors also observed neurotropism in 4 of their cases.³⁹⁶ There may be a poorly differentiated interface between the fascicles and the dermal collagen.³⁹⁷ Some of the cells may have large hyperchromatic nuclei, and some mitoses are common (Fig. 37.20).³⁹⁸ Dermal melanocytosis, in which the cells expressed NKI/C3 but not S100 protein, has been reported in the stroma of neurothekeomas.³⁹⁹ Extensive dystrophic calcification⁴⁰⁰ and ossification have been reported.⁴⁰¹ Osteoclast-like giant cells are present in nearly 40% of cases.³⁸⁰ Several cases of a tumor with extensive ossification and features similar to ossifying neurothekeoma have been called **ossifying plexiform tumor** because the authors believed it was probably a lesion sui generis.⁴⁰² A variant of neurothekeoma, with epithelioid as well as spindle-shaped cells and a cellular morphology, has been reported as a 'cellular neurothekeoma' – a term often used now to include all neurothekeomas.^{379,403,404} The authors speculated that it was an epithelioid variant of pilar leiomyoma, although only three were positive for smooth muscle actin.⁴⁰³

In 1998, Busam and colleagues described an atypical cellular neurothekeoma,³⁸⁵ characterized by at least one of the following features: large size, deep extension of the lesion, infiltrating borders, high mitotic activity (>3 mitoses/10 high-power fields), marked cytological pleomorphism, and signs of vascular invasion.³⁸⁵ Based on a limited number of cases, it appears that surgical excision may be curative.⁴⁰⁵

The immunohistochemical findings are different from those found in nerve sheath myxomas. Neurothekeomas do not express S100 protein, but all express NKI/C3.^{375,379,382} This latter marker is frequently positive in histiocytic tumors, limiting its usefulness.⁴⁰⁶ The marker PGP9.5 (protein gene product 9.5) is often expressed, but some experts do not use it because of its profound lack of specificity.³⁷⁹ Interestingly, anti-PGP9.5 targets ubiquitin carboxyl-terminal esterase L1, an enzyme said to be found exclusively in neurons.⁴ In one study, 89% of cases expressed NSE, and half showed at least focal positivity for smooth muscle actin.³⁷⁹ S100A6 is frequently positive.³⁷⁸ Focal positivity for factor XIIIa has also been noted.^{407,408} One case expressed PG-M1, a reliable histiocytic marker.³⁹⁰ Another recent case expressed the neuroendocrine markers chromogranin and synaptophysin, in addition to neuron-specific enolase and CD56.⁴⁰⁹

Dermoscopy has shown thick, arborizing vessels in cellular neurothekeoma – a finding typical of nodular and cystic basal cell carcinomas that has also been described in hidradenoma and hidroacanthoma simplex.⁴¹⁰

Electron microscopy

There have been conflicting reports of the ultrastructural changes.^{411–413} It appears to be composed of undifferentiated cells with partial features of Schwann cells, smooth muscle cells, myofibroblasts, and fibroblasts, suggesting a divergent differentiation.⁴¹³

Differential diagnosis

Neurothekeoma must be distinguished from plexiform fibrohistiocytic tumor, epithelioid neurofibroma, epithelioid schwannoma, low-grade epithelioid MPNST, epithelioid Spitz nevi, and nevoid melanoma. Neurofibroma, schwannoma, and melanocytic nevi are generally positive for S100, and a significant number of benign and malignant melanocytic lesions express HMB-45, MART-1/melan-A, and tyrosinase. Neurothekeomas are negative for these determinants. The similarities between cellular neurothekeoma and plexiform fibrohistiocytic tumor can be striking, particularly in partial biopsy specimens; in fact, it has been suggested that these may be related lesions. However, Kaddu and Leinweber found that all cellular neurothekeomas expressed podoplanin, in contrast to the negative staining of plexiform fibrohistiocytic tumors.⁴¹⁴ More recently, Fox *et al.* demonstrated that despite the morphologic similarities and similar immunohistochemical profiles between these two tumors (both are NKI-C3, CD10, and, often, PAX2 positive), MiTF is strongly positive in cellular neurothekeomas and negative in plexiform fibrohistiocytic tumors.⁴¹⁵ On the other hand, in the study of Fried *et al.*, two-thirds of 33 cases of neurothekeoma showed only focal or negative reactivity with MiTF.⁴¹⁶ This apparent discrepancy in MiTF staining of neurothekeomas needs to be resolved. Recently reported cases of neurothekeoma with a fascicular configuration resemble dermatofibroma, including occasional overlying epidermal hyperplasia. They differ by the finding of plump, epithelioid cells with abundant cytoplasm and focally prominent nucleoli, the lobulated to micronodular features, and the staining profile, particularly NKI-C3 and MiTF positivity and negative staining for factor XIIIa.³⁹⁴ Another potentially helpful diagnostic stain for neurothekeoma is KBA.62. In a study of 18 neurothekeomas, Suarez and High found that the epithelioid cells of all tumors were KBA.62 positive. However, difficulties could arise from the fact that this marker is also positive in approximately 93% of melanomas, and it is one of those markers that has been particularly helpful in staining desmoplastic melanomas.⁴¹⁷ Those cases of neurothekeoma with significant cytologic

atypia and mitotic activity need to be distinguished from epithelioid MPNST; the features that most favor the latter diagnosis include striking cellular pleomorphism, spontaneous necrosis, or abnormal mitotic figures.

PIGMENTED STORIFORM NEUROFIBROMA

The pigmented storiform neurofibroma, also known as the Bednar tumor, is now regarded as a variant of dermatofibrosarcoma protuberans that shows some neural differentiation. It is discussed further in Chapter 34, page 998.

GRANULAR CELL TUMOR

The granular cell tumor, previously known as granular cell myoblastoma, is an uncommon, benign tumor of disputed histogenesis. It may develop in many anatomical sites:^{418–421} most are found in the oral cavity, especially the tongue, and in the skin and subcutaneous tissue.^{418,422,423} Rare sites include the clitoris⁴²⁴ and the penis.⁴²⁵ There is a female predominance and a predilection for black races. Familial cases are rare.^{426,427} The average age of presentation is 40–50 years, but the tumors may arise in children.^{428–430} Most lesions are asymptomatic solitary skin-colored nodules, less than 2 cm in diameter. Hypertrichosis of a granular cell tumor has been reported.⁴³¹ They are multiple in approximately 10% of cases.^{428,432–439} Sometimes there are associated visceral granular cell tumors⁴⁴⁰ or defects in other organs.^{436,437,441} Multiple granular cell tumors have been associated with neurofibromatosis,^{442,443} growth retardation,⁴³⁰ and Hodgkin's disease.⁴⁴⁴

Morphologically similar tumors are found on the anterior alveolar ridge of neonates, almost exclusively in females.⁴⁴⁵ Occasionally, they are multiple,⁴⁴⁵ or they may involve other areas of the oral cavity.⁴⁴⁶ These gingival giant cell tumors (congenital epulis) may regress spontaneously or following inadequate removal. They are approximately one-tenth as common as the acquired variant.

Malignant granular cell tumors are exceedingly rare, accounting for only 1–3% of all acquired granular cell tumors.^{418,447,448} Very few have been reported in the skin.^{449–456} They may metastasize to regional lymph nodes or more widely.^{426,451} Some pathologists require metastasis to have occurred before accepting a case as malignant.⁴⁵⁷ The atypical granular cell tumor is benign.⁴⁵⁸ Of interest is the report of a patient with neurofibromatosis in whom a malignant granular cell tumor developed.⁴⁵⁹

Some immunohistochemical studies have been interpreted as indicating an origin from a 'neural crest-derived peripheral nerve-related cell',⁴⁶⁰ but most investigators still favor a Schwann cell origin.^{421,461} Ultrastructural studies of gingival giant cell tumors of the newborn have suggested an origin from undifferentiated mesenchymal cells,^{446,462} by analogy, a similar origin has been proposed for the acquired variant.⁴⁴⁶ These theories are not mutually exclusive.^{460,463}

The **polypoid granular cell tumors** of the skin described by LeBoit *et al.* are thought to be from a different cell lineage.⁴⁶⁴ Lazar and Fletcher have since reported a further 13 cases of this entity, which they called 'primitive nonneural granular cell tumors'.⁴⁶⁵ Their cases ranged in age from 5 to 83 years (median, 16 years). They involved mainly the trunk. They ranged in size from 0.2 to 2.8 cm in diameter and were present for months to years prior to removal. One case metastasized to a lymph node, but the patient was disease-free 70 months after lymphadenectomy.⁴⁶⁵ They do not appear to be neural or schwannian in nature.⁴⁶⁵

Histopathology^{418,419,466}

The tumors are non-encapsulated and composed of irregularly arranged sheets of large polyhedral cells with a small central hyperchromatic

Figure 37.21 Granular cell tumor. (A) The epidermal hyperplasia may overshadow the dermal granular cells. (B) The eosinophilic granular cytoplasm is characteristic. (H&E)

nucleus and abundant fine to coarsely granular eosinophilic cytoplasm (Fig. 37.21). Large cytoplasmic granules, surrounded by a clear halo (pustulo-ovoid bodies of Milian), are present in varying numbers in all tumors.⁴⁶⁷ Dermal tumors often extend into the upper subcutis. Cells infiltrate between collagen bundles and may displace them. They surround appendages but may extend into the arrector pili muscle. Rarely, a plexiform or dermatofibroma-like pattern is present.^{468–471} Cytoplasmic borders are not always distinct. The clear cell variant is also very rare, but focal clear cell change is not uncommon in conventional cases.⁴⁷² Prominent lymphoid nodules were present at the periphery in the clear cell variant.⁴⁷² The cytoplasmic granules are periodic acid–Schiff (PAS) positive and diastase resistant. They are also well seen with Movat’s pentachrome technique.⁴⁶⁶ The nuclei contain one or two nucleoli. Elastosis is common in the stroma of granular cell tumors.⁴⁷³

The overlying epithelium often shows prominent pseudoepitheliomatous hyperplasia, which may be misdiagnosed as squamous cell carcinoma if only a superficial biopsy is available for examination.⁴¹⁸ Attempts have been made to quantify the morphometric differences between these two processes.⁴⁷⁴ This epithelial response is usually not present in congenital gingival tumors,⁴⁴⁶ and it is absent in some cutaneous tumors, especially if multiple.⁴³³ The rare granular cell tumors that extend into the epidermis are potential mimics of melanocytic neoplasia. An immunohistochemical panel will distinguish these two processes, if there is any doubt, on light microscopy.⁴⁷⁵

Figure 37.22 (A) Primitive non-neural granular cell tumor (polypoid granular cell tumor). (B) There is some cytological atypia. (H&E)

Congenital gingival tumors have a more prominent vascular stroma, often with perivascular collections of lymphocytes and histiocytes.⁴⁶² The amount of stromal collagen increases as the lesion ages. Small nerve fibers are sometimes found in and around acquired granular cell tumors.⁴³³

The *polypoid granular cell tumors* of the skin are mostly in the upper dermis and associated with an epithelial collarette.⁴⁶⁵ Some tumors are situated more deeply in the reticular dermis with limited extension into the subcutis. They are composed of spindled to ovoid cells with abundant granular, eosinophilic cytoplasm and vesicular nuclei with small prominent nucleoli (Fig. 37.22).⁴⁶⁵ Cytological atypia and scattered mitoses are often features of this tumor.⁴⁶⁴ A majority of polypoid granular cell tumors express NKI/C3, vimentin, PGP9.5, and CD68, and some also express NSE. Several recent papers have reported CD10 positivity in these tumors.^{476,477} They are negative for S100 protein, as well as for epithelial and myoid markers.^{465,476}

Immunohistological studies of granular cell tumors have given conflicting results. Granular cell tumors usually express S100 protein,^{456,478–480} CD68,⁴⁸¹ low-affinity nerve growth factor receptor (NGFR-5),⁴²⁵ microphthalmia transcription factor (MITF),⁴⁸²

inhibin- α ,⁴⁸¹ NSE,⁴⁶⁰ PGP9.5,⁴⁸³ and the melanoma-associated antigen NKI/C3.⁴⁶⁰ Myelin basic protein (MBP) and calretinin have been present in some cases;^{425,484} Bcl-2 positivity has been described.⁴⁸⁵ MBP was absent in all 25 cases in one series.⁴⁶⁰ The cells are negative for myoglobin,^{480,486} HMB-45,⁴⁸² and GFAP.¹⁶⁷ Melan-A is focally positive in rare cases only.⁴⁸² Some reports have suggested the presence of carcinoembryonic antigen (CEA),⁴⁸⁶ but this appears to be a false-positive result due to a related antigen in the tumor cells.^{487,488} The cells are also positive for esterase and acid phosphatase.⁴⁶⁶

There are no well-defined criteria for malignancy. Tumor size greater than 5 cm, vascular invasion, necrosis, and rapid growth are important indicators of malignant behavior.^{440,454} Mitoses, apoptotic cells, and pleomorphic nuclei may also be present, but not necessarily so; they are invariably absent in benign variants.⁴⁵⁵ Cell spindling and angiogenesis have been reported in malignant lesions. So-called atypical variants have one or two of the following features: spindling of the tumor cells, necrosis, diffuse pleomorphism, prominent nucleoli, a high nuclear:cytoplasmic ratio, and a mitotic rate >2 per 10 high-power fields.⁴⁵⁷ Three or more of these findings are present in malignant tumors.⁴⁵⁷ The number of cells positive for Ki-67 and phosphohistone-H3 (PHH3) is higher in atypical forms.^{457,481}

The exact nosological position of the congenital lesion reported as **CD34⁺ granular cell dendrocytosis** is currently unknown.⁴⁸⁹ The patient had numerous papules and plaques on the face and extremities. The lesions were composed of S100⁺, CD34⁺ dermal dendrocytes, with a granular morphology due to an abundance of phagolysosomes and an appearance resembling a granular cell tumor.⁴⁸⁹ A similar case with CD34⁺ cells has been reported as a congenital granular cell tumor.⁴²⁷

On fine needle aspiration cytology, there are groups of large polygonal cells with ill-defined borders, containing fragile, granular cytoplasm. The granules are PAS positive and diastase resistant. The nuclear:cytoplasmic ratio is low, and nuclei are round to oval with fine chromatin, small nucleoli, and sometimes intranuclear inclusions, as previously described by Liu *et al.*^{490,491}

Electron microscopy

The tumor cells are surrounded by a basal lamina.⁴⁴⁰ The cytoplasm contains numerous granules of various sizes and shapes; the majority of these are phagolysosomes.^{421,486,492} Microfilaments and microtubules have been reported.⁴⁹² Angulate bodies may also be found in acquired tumors,⁴⁸⁶ and sometimes these are also found in satellite fibroblasts.⁴⁹³ Congenital tumors have immature mesenchymal cells as well as forms transitional between these and the granular cells.⁴⁴⁶

Differential diagnosis

The granular cell variant of perineurioma is nonreactive for schwannian markers and labels for EMA. Granular cell change can represent a nonspecific degenerative phenomenon, manifesting as numerous secondary phagolysosomes. Such changes can occur in a wide variety of lesions, including dermatofibroma, atypical fibroxanthoma, leiomyoma, leiomyosarcoma, angiosarcoma, melanoma, and basal cell carcinoma. These tumors retain their overall configurational and immunohistochemical properties, and their biologic properties are the same as their conventional counterparts.

MALIGNANT PERIPHERAL NERVE SHEATH TUMOR

Malignant peripheral nerve sheath tumor (MPNST)² is the preferred designation for a tumor that has in the past been called neurosarcoma, neurogenic sarcoma, neurofibrosarcoma,^{494,495} and malignant schwannoma.⁴⁹⁶⁻⁴⁹⁸ This latter tumor is not always included under this 'umbrella' term.⁴⁹⁹ MPNST is a rare tumor, accounting for approximately 2% of all nerve sheath tumors.⁵⁰⁰ Most cases are thought to

arise by malignant transformation of a neurofibroma.³¹⁸ Only two forms of neurofibroma – the plexiform and the massive soft tissue variant – are significant precursors of MPNST.³¹⁸ However, Schwann cells are not the only component of MPNSTs.⁵⁰¹ Other cells contribute to the heterogeneous components present in this tumor.⁵⁰¹ Although tumor is sometimes present in the dermis,^{502,503} this usually represents extension of a growth that originated in the deeper soft tissues.⁵⁰⁴ Superficial tumors have had a better prognosis than deeper ones, in most series.⁵⁰⁵

A variant is the perineurial malignant peripheral nerve sheath tumor derived from perineurial rather than Schwann cells. Only 4% of MPNSTs show perineurial cell differentiation.⁵⁰⁶ The biological potential of the malignant perineurioma is not known because few pure cases have been reported to date.⁵⁰⁷

The t(X;18) translocation found in synovial sarcomas has now been reported in MPNST.⁵⁰⁸

Neurofibromatosis is present in more than 50% of cases of MPNST.^{509,510} It was present in only 22% of patients with MPNST reported from Milan.⁵¹¹ There is a predilection for the deep soft tissues of the proximal extremities of young and middle-aged adults. The mean survival for patients with these tumors is 2 or 3 years.^{512,513} Soft tissue sarcomas, particularly rhabdomyosarcomas, developing in children and adolescents with NF-1 have an aggressive course.⁵¹⁴ In the series of 205 patients from Milan, the disease-specific mortality was 43% at 10 years.⁵¹¹ This series included tumors occurring in all body sites. Recent investigations using high-resolution array-based comparative genomic hybridization have shown that CDK4 gain/amplification and increased FOXM1 protein expression were significant independent predictors for poor survival among MPNST patients.⁵¹⁵ Immunohistochemical staining for insulin receptor substrate (IRS1 and IRS2) and focal adhesion kinase (FAK), proteins involved in cell signaling and cell adhesion pathways, has demonstrated that MPNSTs have elevated levels of IRS2 and FAK and lower levels of IRS1 than neurofibromas; the first two proteins may be involved with malignant transformation in neurofibromas.^{516,520}

Treatment is usually surgical resection. The role of radiotherapy and/or chemotherapy has not been studied in a controlled manner.⁵¹¹

Histopathology

There is usually a spindle cell growth pattern with cells arranged in tight wavy or interlacing bundles (Fig. 37.23).⁵¹⁷ There are sometimes densely cellular areas alternating with more loosely textured areas.⁵¹⁸ A rare plexiform variant has been reported.⁵¹⁹ The cellularity and number of mitoses determine the grading of the tumor.

Figure 37.23 Malignant nerve sheath tumor. This cellular tumor is composed of interlacing bundles of spindle-shaped cells. Several mitoses are present. (H&E)

Purely epithelioid variants have been reported (malignant epithelioid schwannoma).^{520–525} There appears to be a tendency for MPNSTs arising in a benign schwannoma to show epithelioid morphology.⁵²⁶ Cartilaginous differentiation was present in one case.⁵²⁷ Metastatic melanoma needs consideration in the diagnosis.⁵²⁸

Focal divergent differentiation – with the formation of foci of osteogenic sarcoma, chondrosarcoma, angiosarcoma,⁵²⁹ rhabdomyosarcoma, or an epithelial element – is present in approximately 15% of tumors.^{530,531} The epithelial element is usually glandular in type.³²⁹ The presence of rhabdomyosarcomatous elements can be confirmed by immunoperoxidase stains for myoglobin,⁵³² desmin, muscle-specific actin, and myogenin.⁵³³ This variant is known as a ‘triton tumor’.^{525,532–534} More than half of the patients have NF-1.⁵³³ It has a worse prognosis than the classic MPNST. This may be due to its expression of *c-myc*.⁵³³ A breakpoint involving 11p15 (the region of the myogenic differentiation 1 gene) has been identified in one case.⁵³⁵ It should not be confused with the rare neuromuscular hamartoma of infancy composed of nerve fibers admixed with well-differentiated skeletal muscle.⁵³⁶

In the past, the diagnosis of a malignant nerve sheath tumor was difficult, particularly in the absence of a clinical history of neurofibromatosis and in those tumors in which no anatomical relationship to a nerve trunk could be demonstrated. The development of immunoperoxidase techniques has assisted considerably in making a specific diagnosis.⁵³⁷ These tumors contain S100 protein, neuron-specific enolase, neurofilament protein, and MBP, although sometimes this staining is weak.^{495,498} Some cases do not express S100 protein.⁵⁰¹ Tumor cells do not express melan-A.⁵³⁸ Vimentin, AE1/AE3, SOX 10, and EMA may also be present.^{165,167,539} Expression of CD117 is extremely uncommon.^{540,541} Whereas the majority of monophasic synovial sarcomas stain for one or both of cytokeratins 7 and 19, most MPNSTs do not express these cytokeratin subsets.⁵³⁹ A high Ki-67 labeling index (>25%) is associated with a reduced survival rate.⁵⁴²

The *perineurial variant* is composed of spindle cells with long processes disposed in whorls or storiform patterns. Necrosis is sometimes present. Their characteristic immunohistochemical profile is EMA⁺, S100⁺.^{506,507} They are also positive for glut-1 and claudin-1.^{516,543}

Electron microscopy

Electron microscopy shows undifferentiated cells with some features of Schwann and perineurial cells.² Fibroblastic cells have also been identified.^{2,544}

Differential diagnosis

The differential diagnosis of MPNST includes leiomyosarcoma; spindle cell squamous cell carcinoma; dermatofibrosarcoma protuberans; atypical fibroxanthoma; and desmoplastic, spindle cell, and/or neutrotropic melanomas. All but the last group of these tumors can be distinguished by immunohistochemistry or electron microscopy. However, desmoplastic and spindle cell melanomas with ‘neuroid’ features share many characteristics with MPNST. They are ultrastructurally virtually identical (premelanosomes are absent in spindle cell melanomas), and both show negative staining with traditional melanocytic markers HMB-45, MART-1/Melan-A, PNL2, and tyrosinase.⁵⁴⁵ Thus, it may not be possible to distinguish between neuroid melanoma and MPNST in the absence of a pre-existing or concurrent cutaneous melanocytic lesion. This conundrum is underscored by the recent case of an intracranial tumor with features of an MPNST. Subsequent discovery of a patch on the left upper lip led to a skin biopsy that showed desmoplastic melanoma with tumor cells aggregating around and within dermal nerve twigs.⁵⁴⁶ Recent preliminary work using tissue microarrays and comparative genomic hybridization on desmoplastic melanomas and MPNSTs has shown a variety of chromosomal alterations in the two tumors, suggesting that this may be a useful differentiating technique in the future.⁵⁴⁷ From a dermatopathology standpoint, a diagnosis of

MPNST in this context requires the absence of an intraepidermal melanocytic lesion and immunohistochemical and (if possible) ultrastructural evaluation demonstrating an absence of melanocytic differentiation.

Differentiation from epithelioid MPNST with pigment production may create significant difficulties in the distinction from metastatic melanoma; this is particularly the case with myxoid melanoma or clear cell sarcoma. On ultrastructural study, these forms of MPNST show not only the typical ultrastructural features of that entity but also premelanosomes within the pigmented elements. Seventy-five percent of epithelioid MPNSTs are positive for podoplanin,³¹² for which melanomas are negative; however, the remaining 25% of negative-staining cases continue to create diagnostic difficulty.⁵⁴⁸ Other sarcomas with epithelioid cells could resemble epithelioid MPNST, including epithelioid sarcoma, epithelioid leiomyosarcoma, and variants of malignant fibrous histiocytoma. However, these tumors lack podoplanin expression, and other immunohistochemical features often allow clear separation from epithelioid MPNST. SOX 10 is a specific but not very sensitive marker in distinguishing MPNST (usually positive) from synovial sarcoma (usually negative). Difficulties can particularly arise in intraneural tumors, a setting in which synovial sarcomas can demonstrate SOX 10 expression.⁵⁴⁹

HERNIATIONS AND ECTOPIAS

NASAL GLIOMA AND NEURAL HETEROTOPIAS

The unsatisfactory term ‘nasal glioma’ refers to the presence of heterotopic neural tissue, predominantly glial in nature, at or near the root of the nose. Approximately 60% of these lesions are confined to the subcutaneous tissue, whereas 30% are intranasal in location.^{550–552} The remainder have both external and intranasal components. In approximately 20% of cases, intracranial connections are present, sometimes with an associated bony defect in the nasofrontal region,^{553,554} but there is no fluid-filled space connecting with the ventricular system, as in an encephalocele. Nasal gliomas present at birth, or in early infancy, as a red to blue, firm smooth tumor near the bridge of the nose. Those confined to the intranasal region may present later with nasal obstruction or epistaxis or as a nasal polyp.

Rarely, similar tissue has been reported in the scalp,⁵⁵⁵ either as a midline parietal nodule⁵⁵⁶ or as multiple subcutaneous nodules in the scalp.⁵⁵⁷ A ring of dark long hair encircling a congenital scalp lesion (the ‘hair collar sign’) is sometimes present as a marker of an associated encephalocele or heterotopic brain tissue. Hair anomalies may also overlie sequestered meningoceles.⁵⁵⁸ Heterotopic glial tissue has been reported in the subcutaneous tissues overlying T12. There was no associated spinal defect.⁵⁵⁹ The term ‘heterotopic neural tissue’ is the preferred collective term for these lesions and for nasal gliomas.⁵⁵⁶ They are hamartomas, resulting from sequestration of neural tissue early in embryogenesis.⁵⁶⁰

Encephaloceles are abnormal herniations of brain tissue through a bony defect.⁵⁶¹ They are broadly divided into anterior (facial) and posterior (scalp) lesions. In general, an anterior lesion portends a more favorable outcome.⁵⁶² Anterior lesions may rarely present as nodules on the cheek.⁵⁶²

Spinal dysraphism refers to a spectrum of congenital anomalies in which there is incomplete fusion of the midline mesenchymal, bony, or neural elements of the spine.^{563,564} Cutaneous defects may also occur. *Occult* spinal dysraphism is the term used for skin-covered lesions without exposed neural tissue. This defect occurs predominantly in the lumbosacral region. Markers of occult spinal dysraphism include lipomas, dermal sinuses, midline dimples, hemangiomas, hypertrichosis (faun tail),^{563,565} and ependymal rests.⁵⁶⁶

Ependymal rests are relatively common lesions arising in the skin and subcutaneous tissues of the sacrococcygeal region.⁵⁶⁷ There may be overlying dimples or pores. They represent remnants of the embryonic filum terminale externum.⁵⁶⁷ In one case, the ependymal rest presented as a skin tag; this may have been related to the concomitant eccrine hamartoma.⁵⁶⁷ The subcutaneous sacrococcygeal myxopapillary ependymoma arises from these ependymal rests.

The **phakomatous choristoma** is a rare congenital hamartoma of lens tissue.⁵⁶⁸ It presents in newborns or young infants as a subcutaneous mass in the medial lower eyelid. Approximately 20 cases have been reported. They consist of large cuboidal cells with faintly eosinophilic cytoplasm arranged in nests, tubules, and cords set in a fibrotic stroma. Some nests contain proteinaceous pink material, with secondary dystrophic calcification. Some cells show vacuolization and degenerative changes. The epithelial cells express S100 protein but not cytokeratin or epithelial membrane antigen.⁵⁶⁸

The meningeal-cutaneous relationships in anencephaly have been reviewed.⁵⁶⁹ This study is mentioned for completeness.

Histopathology^{560,570}

In nasal gliomas, there are islands of neural and fibrovascular tissue in the subcutis. The neural tissue is composed of astrocytes enmeshed in a neurofibrillary stroma (Fig. 37.24). Multinucleate astrocytes are not uncommon, but neurons are usually inconspicuous and few in number. They were the predominant element in one case.⁵⁷¹ The nodules are interlaced with vascular fibrous septa. A markedly sclerosed stroma may be seen in older lesions.⁵⁷² Calcification and sweat duct hyperplasia are two other rare associations.⁵⁷³

Heterotopic neural islands occurring on the scalp may be surrounded by a capsule that structurally resembles the leptomeninges.^{556,574} Clusters of ependymal cells with central vascular channels and myxoid stroma (myxopapillary ependymal rests) are found rarely in the sacrococcygeal region (Fig. 37.25).⁵⁷⁵

Immunoperoxidase staining demonstrates GFAP and S100 protein in the glial tissue.⁵⁷²

CUTANEOUS MENINGIOMA

Meningiomas (cutaneous meningothelial tumors, cutaneous heterotopic meningeal nodules) are found only rarely in extracranial sites, including the skin.^{576–581} The scalp, forehead, and paravertebral areas are most commonly involved. Three distinct clinicopathological groups have been recognized.⁵⁷⁹ *Type I lesions* arise in the subcutaneous tissue of the scalp, forehead, and paravertebral region. They are usually present at birth and are thought to be derived from ectopic arachnoid cells misplaced during embryogenesis. A familial occurrence has been reported.⁵⁸² This group includes lesions with only scattered meningothelial cells in a collagenous nodule (acelic meningeal hamartoma), lesions with a rudimentary cystic channel (rudimentary meningocele variant), and those with well-circumscribed nodules resembling intracranial meningiomas.^{558,561,583–590} *Type II lesions* are found in adults around sensory organs of the head (periorbital, aural, and paranasal) and along the course of cranial and spinal nerves. They are thought to be derived from nests of arachnoid cells that are found along the course of these nerves after they penetrate the dura. *Type III lesions* represent the direct cutaneous extension or distant metastasis of an intracranial tumor.^{570,591–593}

Primary cutaneous meningioma has been reported in association with von Recklinghausen's disease⁵⁹⁴ and also in association with a sinus pericranii.⁵⁹⁵ Another rare presentation is as an aural polyp.⁵⁹⁶

Histopathology⁵⁷⁹

Whereas type I lesions are usually confined to the subcutis, type II and III tumors may also involve the dermis. Some type I lesions consist

Figure 37.24 Heterotopic glial tissue admixed with collagen bundles. (A) This lesion was removed from the occipital region. (H&E) (B) The pale pink glial fibers contrast with the green stromal collagen. (Masson trichrome) (C) Another case with an inset stained for glial fibrillary acid protein. (H&E with immunoperoxidase inset)

Figure 37.25 Ependymal rest. Cuboidal cells are aggregated around mucinous foci. This lesion was found in the sacrococcygeal region and was associated with an epithelial-lined sinus. (H&E)

merely of irregular strands of meningotheial cells set in a collagenous stroma,⁵⁹⁷ whereas others resemble type II and III tumors in being circumscribed and more cellular, akin to intracranial meningiomas and including spindle cell areas and meningotheial whorls (**Fig. 37.26A**). Psammoma bodies are variable in number (**Fig. 37.26B**). Inflammatory cells may be present in type II and III lesions.

When meningoceles and related malformations are studied, a range of tissue types can be identified, including dura-like tissue, blood vessels, lipoma formation, hypertrophy of the arrector pili muscle, nerve fibers, meningotheial cells, and neural tissue.⁵⁶¹ The case in an infant who presented with several nodules on the face composed of meningeal tissue, smooth muscle, and connective tissue was regarded as a hamartoma of ‘cephalic neural crest-derived tissues’.⁵⁹⁸

Immunoperoxidase studies for S100, vimentin, and epithelial membrane antigen have been positive.^{576,577,599} A recent case was S100⁺ but positive for EMA and vimentin.⁵⁹⁰ Ultrastructural studies have shown a similar appearance to intracranial meningiomas.^{578,579}

Barr and colleagues described three cases of an unusual cutaneous tumor with a superficial resemblance to a meningioma or the canine hemangiopericytoma.⁶⁰⁰ The tumors had a whorled configuration of spindle cells, some concentrically arranged around blood vessels. Only vimentin positivity was present.

Differential diagnosis

Due to the variability of microscopic presentations of meningioma, these lesions can be confused with appendageal carcinomas, epithelioid cell or spindle cell sarcomas, peripheral nerve sheath tumors (especially perineurioma), or amelanotic melanoma. Ultrastructural study can be helpful because meningiomas feature complex interdigitated cell membranes, linked by well-formed tripartite desmosomes – features not seen in the other alternative tumors. Immunohistochemistry is more problematic because of the heterogeneous staining profile of meningiomas. Thus, in addition to the S100, EMA, and vimentin positivity noted previously, meningiomas can also express p63,⁶⁰¹ claudin-1, podoplanin, glut-1, and type IV collagen, creating overlap situations with several other tumors. P63 in particular is expressed in dural-based meningiomas and hence is positive in type II and III meningiomas – creating potential issues in the differentiation from epidermal and adnexal tumors.⁶⁰² Melan-A negativity can help in the distinction from

Figure 37.26 Meningioma. (A) This is a cellular lesion that includes spindle cell areas and meningotheial whorls. (H&E) (B) Psammoma bodies are particularly numerous in this example.

melanoma, whereas results of CD31, CD34, CD68, smooth muscle actin, and desmin stains (also negative) can exclude tumors of vascular, ‘histiocytic’, or smooth muscle origin.⁶⁰³

NEUROENDOCRINE TUMORS

Cutaneous neoplasms of neuroendocrine origin are almost invariably malignant. Malignant tumors may be primary – neuroendocrine carcinoma and Merkel cell carcinoma – or secondary, usually from the lung. Because the earlier literature used the terms neuroendocrine carcinoma and Merkel cell carcinoma synonymously, it is difficult, in retrospect, to comment on these early cases. Furthermore, immunoperoxidase markers were not at the sophisticated level they are today.

Primary neuroendocrine carcinoma of the skin is exceedingly rare. There is a recent case involving the male nipple that was initially misdiagnosed as Merkel cell carcinoma because of their histological similarities.⁶⁰⁴ Because the tumor expressed neuroendocrine markers (synaptophysin, NSE, and CD56), but not CD20, it was reclassified as neuroendocrine carcinoma.⁶⁰⁴ The other neuroendocrine marker, chromogranin A, was not performed.

Before discussing Merkel cell carcinoma, brief descriptions of the rare cutaneous paraganglioma and neuroendocrine adenoma are given.

CUTANEOUS PARAGANGLIOMA

Paragangliomas are neuroendocrine tumors derived from the autonomic nervous system.⁶⁰⁵ Approximately 10% are extra-adrenal in location. Carotid body paragangliomas are one such group. The first case of a primary cutaneous paraganglioma was reported in 2006.⁶⁰⁵ It was a dermal nodule on the scalp of a 10-year-old boy. There was no evidence of the multiple endocrine neoplasia syndrome. Cutaneous metastasis to the scalp from an extra-adrenal paraganglioma of the sacrum has also been reported.⁶⁰⁶

Histopathology

Paragangliomas are characterized by nests of large polygonal cells with central oval nuclei and abundant eosinophilic and granular cytoplasm.⁶⁰⁵ The nests are separated by thin fibrous septa, giving a 'zellballen' (cell-ball) appearance.

The cells express vimentin, neuron-specific enolase, chromogranin, synaptophysin,⁶⁰⁵ and CD56.⁶⁰⁷ Sustentacular cells are positive for S100 and glial fibrillary acidic protein and negative for cytokeratin, EMA, and HMB-45.⁶⁰⁷

NEUROENDOCRINE ADENOMA

Neuroendocrine adenomas are rare tumors of the middle ear of uncertain nature. A case has been reported in the external ear that presented as a granular mass composed of closely packed glands, in a somewhat trabecular pattern. The glands were lined by cuboidal cells with abundant granular cytoplasm.⁶⁰⁸ An amorphous pink substance was present in scattered glandular lumina. Pagetoid spread of tumor cells was present, but the tumor behaved in a benign manner.

The cells expressed neuron-specific enolase and synaptophysin but not S100 protein, cytokeratin 20 (CK20), or chromogranin.⁶⁰⁸

MERKEL CELL CARCINOMA

In 1972, Toker reported five cases of this tumor as trabecular carcinoma.⁶⁰⁹ Several years later, on the basis of the electron microscopic findings of neurosecretory granules, Tang and Toker suggested that the tumor had a Merkel cell origin.⁶¹⁰ Because a Merkel cell origin is not established beyond doubt,⁶¹¹ and because a trabecular pattern is not usually a dominant feature, the designation 'neuroendocrine carcinoma' has been favored by some.^{612,613} Cases continue to be reported that indicate that neuroendocrine carcinoma is not synonymous with Merkel cell carcinoma.^{604,614} Another term used is 'primary small-cell carcinoma of the skin'.⁶¹⁵ Most reports in the literature use the term 'Merkel cell carcinoma'.

Merkel cells, the presumptive cell of origin of Merkel cell carcinoma, are primarily localized in the basal layer of the epidermis, and they are concentrated in touch-sensitive areas in glabrous and hairy skin.⁶¹⁶ They cannot be identified by standard histological staining (hematoxylin and eosin (H&E)). Immunohistochemistry or electron microscopy analysis is required.⁶¹⁶ They take part in mechanoreception, but little is known about their interactions with other epidermal cells. They synthesize numerous peptides.⁶¹⁶ Interestingly, in a study using rats, the electromagnetic radiation from a cellular telephone led to significantly higher exocytotic activity in Merkel cells compared with a control group.⁶¹⁷

Merkel cell carcinoma usually arises on the sun-exposed skin of elderly patients, particularly on the head and neck and extremities.⁶¹⁸⁻⁶²⁰

Perianal and eyelid involvement have been recorded.^{621,622} The synchronous onset of multiple cutaneous lesions, localized to the scalp, has been reported.⁶²³ It occurs, rarely, in children.⁶²⁴ Its incidence in the United States in 2001 was estimated to be 0.44 cases per 100,000.⁶²⁵ Rare associations include chronic lymphocytic leukemia,⁶²⁶⁻⁶²⁸ chronic arsenicism,^{629,630} HIV infection,⁶³¹⁻⁶³³ postmastectomy lymphedema,⁶³⁴ sarcoidosis,⁶³⁵ a paraneoplastic syndrome,⁶³⁶ therapeutic immunosuppression,⁶³⁷⁻⁶³⁹ and ectodermal dysplasia.^{640,641} It is uncommon in organ-transplant recipients.⁶⁴² There is a relatively high incidence of second neoplasms in patients with Merkel cell carcinoma;^{628,643,644} risks for basal cell carcinoma and chronic lymphocytic leukemia are significantly increased.⁶⁴⁵ A collision tumor composed of Merkel cell carcinoma and lentigo maligna melanoma has been reported.⁶⁴⁶ Two cases of Merkel cell carcinoma of the parotid gland, each associated with a Warthin tumor, have been reported.⁶⁴⁷ There has been a female preponderance in some series and a predilection for males in others.⁶⁴⁸⁻⁶⁵² The tumors are often clinically indistinguishable from other skin cancers. They may have a reddish, nodular appearance that sometimes resembles an angiosarcoma or granulation tissue.^{653,654} They average 2 cm in diameter, although 'giant' and small variants have been recorded.^{655,656} The acronym AEIOU (asymptomatic, expanding rapidly, immune suppression, older than 50 years, and ultraviolet-exposed site) has been proposed as a useful reminder of the clinical features.⁶⁵⁷

Local recurrences occur in approximately one-third of cases. The tumor spreads to the regional lymph nodes in up to 75% of cases,^{618,658,659} and distant metastasis with eventual death occurs in one-third or more.⁶⁶⁰ There is also a group of patients who present with lymph node involvement of Merkel cell carcinoma with an unknown primary site. Interestingly, the overall survival of stage IIIB patients with this scenario is improved compared to that of stage IIIB patients with known primary sites.⁶⁶¹ Sentinel lymph node biopsy detects tumor spread in one-third of patients whose tumors would have otherwise been understaged.^{662,663} There was significant prognostic benefit of adjuvant nodal therapy, but only when the sentinel lymph node biopsy was positive.⁶⁶³ Common metastatic sites include regional lymph nodes, skin, liver, lungs, bones, and brain.⁶⁶⁴ Leukemic dissemination of tumor cells has been reported in a patient with systemic lupus erythematosus.⁶⁶⁵ Spontaneous regression of both primary and metastatic tumors has been reported.⁶⁶⁶⁻⁶⁷² A role for T-cell-mediated immunity and apoptosis has been suggested in these cases.⁶⁷² In a large series reported from the Memorial Sloan-Kettering Cancer Center, the overall 5-year disease-specific survival rate was 75%.⁶⁷³ In another series, the 5-year relative survival was 75, 59, and 25% for localized, regional, and distant Merkel cell carcinoma, respectively.⁶⁵⁰ Female sex, limb presentation, localized disease, and younger age were positive predictors of survival.⁶⁵⁰ In another study, adverse prognostic features included tumor size, invasion into subcutaneous fat, and a heavy lymphocytic infiltrate.⁶⁵² Advanced clinical stage is another adverse prognostic feature.⁶⁷⁴ According to a study by Hall *et al.*, when considered as a binary variable, p63 expression is a significant risk factor for shortened survival, although the authors admit that larger studies will be needed to determine if p63 status should be included in Merkel cell carcinoma staging.⁶⁷⁵ This same study shows that Merkel cell polyomavirus (MCPyV) status does not correlate with survival.⁶⁷⁵ No significant difference in outcome has been found in patients who have Merkel cell carcinoma in combination with another cutaneous tumor.⁶⁷⁶ Merkel cell carcinoma involving lymph nodes and lacking an identifiable primary site may result from regression of a cutaneous primary, although an origin in lymph nodes may be the explanation in other cases.^{677,678} Cases in other ectopic sites have also been reported.⁶⁷⁸

Ectopic peptide production is not uncommon (see later),⁶⁷⁹ but the levels are not high enough to produce a clinical endocrinopathy.⁶⁸⁰ Paraneoplastic syndromes are rare.⁶⁸¹

Nearly 50% of Merkel cell carcinomas exhibit trisomy 6.⁶⁸² A distal deletion involving chromosome 1p35–p36 is also quite common – a feature shared with other neoplasms of neural crest derivation.⁶⁸³ In one-third of cases, there is loss of the whole of chromosome 10 or part of its long arm.⁶⁸⁴ Other chromosomes implicated include 18q and 20.⁶⁸⁵ The T1796A *BRAF* mutation is absent.⁶⁸⁶ The chemoresistance gene *ABCG2* is expressed only very focally and in a small number of cases of Merkel cell carcinoma.⁶⁸⁷

Now that tumor cell lines have been established in the laboratory, it is hoped that further studies may give some insight into the origin of this enigmatic tumor.^{688,689} There is no evidence of an association with Epstein–Barr virus.⁶⁹⁰ In 2008, a report appeared linking Merkel cell carcinoma to a new polyomavirus that the authors called Merkel cell polyomavirus (MCV).⁶⁹¹ They detected MCV sequences in 80% of the tumors (10) studied.⁶⁹¹ They concluded that the virus ‘may be a contributing factor in the pathogenesis’ of this tumor.⁶⁹¹ There is a tendency for MCPyV⁺ Merkel cell carcinomas to be located preferentially on the extremities.⁶⁹² There may be significant variations in frequency of MCPyV in Merkel cell carcinomas among different populations. Thus, the frequency of this virus is quite high in Europe and North America, whereas in Australia, the incidence of MCPyV (as detected by immunohistochemistry) is relatively low, suggesting a sun-dependent pathway in Merkel cell carcinoma development.⁶⁹³ The kinetics of this tumor have been studied.⁶⁹⁴ There is superficial aneuploid DNA content. Apoptosis follows proliferation in superficial compartments, being less variable and proliferation-independent in the deeper compartments.⁶⁹⁴ The WNT signaling pathway is not implicated in tumorigenesis.⁶⁹⁵

It is generally agreed that the primary tumor should be treated aggressively.^{696,697} The treatment of choice for Merkel cell carcinoma is wide surgical excision combined with radiotherapy.^{651,698} Adjuvant nodal therapy appears to have a benefit when sentinel lymph node biopsy is positive. More specific recommendations were made in a 2007 report that recommended margins of 1 cm when the tumor was <2 cm diameter and 1- or 2-cm margins for larger tumors.⁶⁹⁹ Radiotherapy to the primary site was recommended for tumors >2 cm in diameter. This contrasts to other studies that have found that adjuvant local or locoregional radiotherapy has resulted in a better disease-free survival compared with surgery alone.^{700–702} Tumor size was not specifically mentioned in these reports. Radiotherapy alone for inoperable tumors is the treatment of choice.^{703–705} Earlier studies suggested that the role of postoperative radiotherapy was unclear⁷⁰⁶ and that surgery was the primary treatment.⁶²⁵ In support of this is a study using Mohs micrographic surgery, in which radiotherapy seemed to confer no additional benefit.⁷⁰⁷

There is an anecdotal report of the complete remission of Merkel cell carcinoma of the scalp with local and regional metastases after topical treatment with dinitrochlorobenzol.⁷⁰⁸ It has been said that systemic chemotherapy should be restricted to clinical trials,⁷⁰² although in the past it was used for patients with metastatic or locally advanced disease.⁷⁰⁹ A high incidence of toxic death due to chemotherapy has been reported in the literature.⁷¹⁰ However, the recent finding of mutations in the platelet-derived growth factor receptor- α (*PDGFRA*) gene in one-third of the cases tested raises the possibility that the kinase inhibitor imatinib mesylate may be effective in these cases.⁷¹¹

Histopathology^{618,712}

The tumor is composed of small, round to oval cells of uniform size with a vesicular nucleus and multiple small nucleoli (Fig. 37.27). Mitoses and apoptotic bodies are usually numerous.⁷¹³ The cytoplasm is scanty and amphophilic, and the cell borders are vaguely defined. Tumor cells may be larger in recurrences after radiotherapy.⁷¹⁴ An initial large cell variant also occurs.⁷¹⁵ A few tumors have scattered areas with

Figure 37.27 (A) Merkel cell carcinoma. (B) The cells are small, with indistinct cytoplasmic borders and a hyperchromatic nucleus. (H&E)

Figure 37.28 Merkel cell carcinoma. Sheets of small cells with hyperchromatic nuclei extend throughout the dermis. (H&E)

spindle-shaped nuclei. The cells are present as sheets and solid nests, infiltrating the entire dermis and sometimes extending into the subcutis (Fig. 37.28). Examples of Merkel cell carcinoma have primarily involved the subcutis, mimicking panniculitis.⁷¹⁶ Some authors have attempted to define three distinct patterns of histological

differentiation: trabecular, small cell, and intermediate. Overlap features are common, and the trabecular pattern may be limited to the peripheral areas of the tumor.⁷¹⁷ Pseudorosettes are quite uncommon.⁷¹⁸ There is a dissociation of tumor cells in poorly fixed areas. Other features include focal necrosis, particularly in large tumors, frequent involvement of dermal lymphatics,⁷¹⁷ and a scattered infiltrate of lymphocytes and sometimes plasma cells. Vascular proliferation is present in approximately 20% of cases.⁷¹⁹ Increased vascular density is associated with a worse prognosis.⁷²⁰ Strongly hematoxyphilic blood vessels, due to nuclear DNA deposition from tumor necrosis (the Azzopardi phenomenon), are most uncommon.⁷²¹ Stromal desmoplasia is a rare finding.⁷²² Amyloid has been demonstrated in a few tumors.^{723,724} Focal argyrophilia is sometimes present, and this is enhanced by fixation in Bouin's solution.⁷¹³

The overlying epidermis is ulcerated in approximately 20% of cases. Sometimes there is epidermal hyperplasia. Epidermotropism of tumor cells is uncommon.^{611,642,725-727} Epidermal involvement was present in 11 of 132 cases in one series.⁷²⁸ Several cases have been reported in which the tumor cells were confined exclusively to the epidermis.^{729,730} Cases with prominent epidermal involvement have been used as evidence of a Merkel cell origin of these tumors.⁷²⁶ Overlying and contiguous Bowen's disease has also been reported,^{618,731,732} as has the admixture of a Merkel and squamous cell carcinoma.⁷³³⁻⁷³⁵ No transition was seen between the two cell types.⁷³⁴ Bowen's disease and concurrent intraepidermal Merkel cell carcinoma have been reported. There was no dermal component of either tumor.⁷³⁶ Another rarity is the finding of a tumor composed of Merkel, squamous, and basal cell carcinoma.⁷³⁷ Areas that resemble basal cell carcinoma are not uncommon.⁷³⁸ This can lead to misdiagnosis on small biopsy specimens and on frozen sections.^{738,739} Patients with Merkel cell carcinoma have often had numerous skin cancers in the past.⁷³⁴ Small swirls of squamoid differentiation,⁷⁴⁰ and even sweat duct differentiation,^{728,731,741,742} are occasionally seen within the tumor. Merkel cell carcinoma with squamous and sarcomatous differentiation is another rare finding.⁷⁴³ Tripartite differentiation (squamous, glandular, and melanocytic) has been recorded.⁷⁴⁴ This has led to the suggestion that the tumor arises from a primitive cell that can differentiate in either a neuroendocrine or a sudoriferous direction.⁷³¹ Prominent microcystic features mimicking eccrine carcinoma have been reported.⁷⁴⁵ Other exceedingly rare patterns of differentiation include skeletal muscle, leiomyosarcomatous, fibrosarcomatous, lymphoepithelioma-like, and atypical fibroxanthoma-like.⁷⁴⁶⁻⁷⁵² A Merkel cell carcinoma with heterologous rhabdomyoblastic differentiation has been recently described; in this case, immunohistochemistry for Merkel cell polyomavirus large T-antigen was diffusely positive.⁷⁵³ Well-differentiated follicular structures were present in one of these cases.⁷⁴⁸ They have since been reported in the more usual type of Merkel cell carcinoma.⁷⁵⁴ Cases of Merkel cell carcinoma arising in an epidermal cyst^{755,756} and others associated with a trichilemmal cyst have been reported.^{757,758} *In situ* Merkel cell carcinoma was present in a trichilemmal cyst in one case.⁷⁵⁹

Examination of the sites of a regressed lesion shows perivascular lymphocytes, some lymphoid nodules, variable numbers of foamy histiocytes, and some fibrosis. No tumor cells remain.⁶⁷⁰ In partial regression, there is usually a heavy lymphocytic infiltrate with prominent apoptosis of tumor cells and some fibrosis.⁷⁶⁰

Histological features associated with a worse survival rate include lymphovascular invasion, high tumor mast cell numbers,⁷⁶¹ increased vascular density,⁷²⁰ small cell size, and a high mitotic rate.⁶⁷⁴ The expression of bcl-2, bax, and p53 did not correlate with survival in one study,⁷⁶² although in another small series, the presence of p53 did correlate with increased recurrence/death.⁷⁶³ This tumor expresses Cox-2 in low levels, and its expression is not a prognostic factor.⁷⁶⁴ The expression of p63, survivin, and Ki-67 is associated with a worse prognosis.⁷⁶⁵⁻⁷⁶⁸ High expression of certain matrix metalloproteinases (MMP-1 and MMP-3) may influence the invasive and metastatic

Figure 37.29 Merkel cell carcinoma. Paranuclear filaments are seen as small globules ('dots'). (Immunoperoxidase preparation for cytokeratin)

potential of this tumor.⁷⁶⁹ A more recent, large tissue microarray study found an increase in CXCR4 and survivin expression in local/regional nodal Merkel cell carcinoma metastases compared to primary and distant metastatic lesions, suggesting a role for these proteins in tumor progression; the investigators were not able to confirm a similar role for bcl-2 or E-cadherin in their study.⁷⁷⁰

Merkel cell carcinomas need to be differentiated histologically from anaplastic primary and secondary tumors; therefore, there have been numerous immunoperoxidase studies assessing the specificity of various markers.^{771,772} The variability in the reported results for the same marker probably reflects the different sensitivity of the techniques used and the level of specificity of the monoclonal antibodies. Most tumors are positive for neuron-specific enolase^{740,773} and epithelial membrane antigen.⁷⁷¹ Cytokeratin is usually present as paranuclear globules (Fig. 37.29),⁷⁷⁴⁻⁷⁷⁷ which are present in mitotic as well as interphase cells.⁷⁷⁸ Both the CAM5.2 and CK20 stains will show this paranuclear dot-like immunoreactivity.^{779,780} Regarding immunohistochemical staining results and their possible relationship to the MCPyV status of a tumor (positivity or negativity), high-percentage CK20 positivity is comparable in both MCPyV⁺ and MCPyV⁻ tumors. CD117 positivity is somewhat more common among MCPyV⁺ tumors, whereas CD19 positivity is more common among MCPyV⁻ tumors; there is no significant difference in expression of stromelysin-3 between the two.⁶⁹² Interestingly, CK19 also produces a paranuclear dot-like stain and may be positive in CK20⁻ cases.⁶⁹² CK20 was initially regarded as a sensitive and specific marker for Merkel cell carcinoma, which allowed distinction from other small cell carcinomas.⁷⁸¹⁻⁷⁸⁴ However, one study has shown that one-third of small cell carcinomas of the lung are positive for CK20.⁷⁸⁵ In this same study, 28 of 33 of the lung tumors stained for thyroid transcription factor-1 (TTF-1), but none of the 21 Merkel cell carcinomas stained.⁷⁸⁵ Other studies have confirmed the value of a negative TTF-1 in distinguishing Merkel cell carcinoma from other small cell carcinomas.^{786,787} Positive staining for CK20 and neurofilaments, performed in association with negative TTF-1, completes this distinction between the two tumors.⁷⁸⁷ MOC-31, an antibody that recognizes epithelial cell adhesion molecule (Ep-CAM), can be positive in both tumors.⁷⁸⁸ A series of 7 cases of CK20⁻/CK7⁺ Merkel cell carcinomas has been described.⁷⁸⁹ All tumors expressed synaptophysin.⁷⁸⁹ CK20 can also be used for the detection of micrometastases in lymph nodes.⁷⁹⁰ It improves the detection of these deposits.^{791,792} Tumor cells may also stain with Ber-EP4, an antibody directed against an epithelium-specific membrane antigen.⁷²⁸ CD117 is expressed as granular cytoplasmic staining in 55-95% of cases.^{779,793-796} Nuclear HUR is expressed in Merkel cell carcinoma and normal skin,

Figure 37.30 Merkel cell carcinoma. Apoptotic tumor cells can be seen. (H&E) The insets show dot positivity with CAM5.2 and cytoplasmic positivity for synaptophysin. (Immunoperoxidase stains)

whereas *cytoplasmic* staining is found only in a subset of tumors but not normal skin.⁷⁹⁷ Neurofilaments,⁷⁹⁸ chromogranin,^{799–801} synaptophysin, guanine nucleotide-binding proteins,⁸⁰² CD171,⁸⁰³ CD24,⁸⁰³ CD56,⁸⁰⁴ and polypeptides such as calcitonin,⁸⁰⁵ gastrin,⁸⁰⁶ somatostatin, and corticotropin are sometimes present (Fig. 37.30).⁶¹² Chromogranin was present in all 20 cases in one series.⁸⁰⁷ CD99 was detected in 11 of these cases.⁸⁰⁷ Expression of CD44 may indicate a metastatic potential.⁸⁰⁸ Acetylcholine receptors are also expressed.⁸⁰⁹ The tumor cells are negative for S100 protein, laminin, CD45 (leukocyte common antigen),⁷⁷⁰ and metenkephalin,^{680,775} with the latter being a marker for normal Merkel cells. Tumor cells often contain high levels of bcl-2 protein.^{810,811} The cells of secondary ‘oat-cell’ carcinomas and carcinoids, some of which are spindle shaped, usually have more cytoplasm; they may be immunoperoxidase positive for bombesin, leucine, enkephalin, and β -endorphin – markers that are absent in Merkel cell carcinomas.⁷⁷²

Newer immunohistochemical markers (or newer uses for established markers) include antibody to OCT4, a transcription factor that stains germ cell and some neuroendocrine tumors. In one study, this agent stained 87% of cases, with varying intensity and percentage of positive cells – most showing moderate intensity in more than 20% of cells.⁸¹² PAX5 and TdT are normally used to diagnose lymphoblastic leukemia/lymphoma. When used in staining Merkel cell carcinomas and pulmonary small cell carcinomas, a high percentage of both are positive for TdT, but PAX5 is much more likely to be positive in Merkel cell carcinoma than in pulmonary small cell carcinomas. This would be a potentially confusing result when lymphoma is a diagnostic consideration, but when deciding between these small cell carcinomas, a metastatic lesion that is PAX5 negative would favor pulmonary small cell carcinoma.⁸¹³ Both monoclonal and polyclonal PAX8 (a nephric cell linkage transcription factor and marker for renal cell carcinoma, Müllerian, and thyroid tumors) show positive nuclear staining in Merkel cell carcinoma.⁸¹⁴

In one case, the nodal metastasis of a Merkel cell carcinoma of the skin showed rhabdomyosarcomatous differentiation.⁸¹⁵

Dermoscopy of Merkel cell carcinoma has been described as a structureless, cherry-red lesion with a few fine blood vessels. Another recent report of two lesions that eventually underwent regression described irregular linear vessels, some curved (‘horseshoe-like’), over a pink to cherry-colored, homogeneous base; white streaks were noted in the central portion of one of the lesions.⁶⁷¹

Electron microscopy

The tumor cells contain dense core neurosecretory granules in the cytoplasm,⁸¹⁶ but these tend to be lost in formalin-fixed material.⁸¹⁷ A characteristic feature is the presence of paranuclear aggregates of intermediate-sized filaments.^{818,819} Complex intercellular junctions and cytoplasmic spinous processes are also present.^{618,820,821}

Differential diagnosis

The microscopic differential diagnosis includes melanoma, lymphoma, cutaneous small cell epithelial tumors (including small cell squamous cell carcinoma, basal cell carcinoma, or sweat gland carcinoma), peripheral neuroepithelioma (PNET), and metastatic small cell neuroendocrine carcinoma. Nodular aggregates of cells in Merkel cell carcinoma can also resemble the nests of melanoma. This is particularly so when tumor cell aggregates are identified in the vicinity of the epidermal junctional zone or within the epidermis. The separation sometimes found around tumor islands can also mimic the cleaving artifact of basal cell carcinoma. Cases showing evidence of ductal differentiation, or entrapment of existing eccrine sweat glands by tumor, can suggest a sweat gland carcinoma, and pseudorosette formation can mimic the changes of peripheral neuroepithelioma.

Nuclear details can be important in leading to a diagnosis of Merkel cell carcinoma because the rounded contours and finely dispersed chromatin are quite distinctive and, in well-prepared sections, are of great help in separating these lesions from melanoma, lymphoma, or cutaneous small cell epithelial tumors. Molding of tumor cells and evidence for eccrine or squamous differentiation, when present, provide a further argument against melanoma, as does the lack of junctional cellular proliferation lateral to the main tumor mass. Broad epidermal connections favor squamous cell carcinoma, whereas well-developed peripheral palisading of tumor islands points to a diagnosis of basal cell carcinoma. PNETs, in contrast to Merkel cell carcinoma, may contain true Homer Wright rosettes with central neurofibrillary material. Electron microscopic demonstration of neurosecretory granules also helps to exclude melanoma, lymphoma, and cutaneous epithelial tumors, including sweat gland carcinomas; perinuclear filament whorls are not seen in sweat gland tumors.

Immunohistochemical findings of punctate cytokeratin staining and positivity for neuroendocrine markers distinguish Merkel cell carcinoma from melanoma, lymphoma, or cutaneous small cell epithelial tumors. Melanoma is usually positive for S100 and vimentin; this has rarely been reported in Merkel cell carcinoma. Other melanocyte markers (e.g., HMB-45 and tyrosinase) are also helpful in distinguishing the two tumors. Leukocyte common antigen is positive in lymphomas and negative in Merkel cell carcinomas, and it is a good screening stain when initially presented with a problematic lesion. Basaloid eccrine carcinomas sometimes express neuron-specific enolase, a potential diagnostic pitfall if other keratin or neuroendocrine markers are negative or equivocal. PNETs can be distinguished from Merkel cell carcinoma because of their negativity for keratins (including CK20) and EMA and their positivity for vimentin and CD99; however, CD99 is also positive in approximately 50% of Merkel cell carcinomas. Molecular analysis can also aid in this distinction; Merkel cell carcinomas, especially those that are positive for MCPyV by immunohistochemical staining with the antibody CM2B4, do not show the EWS/FLI-1 rearrangement characteristic of PNET.⁸²²

MALIGNANT PRIMITIVE NEUROECTODERMAL TUMOR

The term ‘malignant primitive (peripheral) neuroectodermal tumor’ (MPNET) is the preferred designation for a rare small cell malignancy of the skin that differs from Merkel cell carcinoma on

immunohistochemical and ultrastructural features.⁸²³⁻⁸²⁶ Other terms used for this tumor include 'malignant neuroepithelioma'⁸²⁷ and 'peripheral neuroepithelioma'.

Extraskeletal Ewing's sarcoma (ES) and MPNET are generally regarded as two ends of a morphological spectrum of the same biological entity.⁸²⁸⁻⁸³⁰ They both contain the cell surface product of the *MIC2* gene, CD99, and both have a consistent chromosomal translocation t(11;22)(q24;q12), found in up to 90% of all cases.^{831,832} Variant translocations, all of which involve the *EWS* gene on chromosome 22q12, have been reported.⁸³¹ Rearrangement of the *EWS* gene can be detected using fluorescent *in situ* hybridization probes for *EWSR1* on paraffin-embedded tissue.⁸³³ This gene rearrangement can also be found in desmoplastic small round cell tumor and clear cell sarcoma.⁸³³

Most MPNETs/EWs are situated in the deep soft tissues.⁸²⁷ The subcutis and dermis are involved quite uncommonly.^{834,835} The peak incidence is in the 20s, with a slight male predilection.⁸³⁶ Most involve the trunk and lower extremities. The vulva and vagina are uncommonly involved.^{836,837} They are highly aggressive tumors that eventually metastasize widely. The overall 5-year survival rate for lesions designated as extraskeletal Ewing's sarcoma was 61% in one series.⁸³⁸ A

younger age and wide initial surgical excision correlated with improved overall survival.⁸³⁸ Superficial Ewing's sarcomas have a reasonably good prognosis.⁸³⁹

Histopathology

Malignant primitive neuroectodermal tumors are composed of sheets of hyperchromatic cells with small amounts of cytoplasm. Homer Wright rosettes are frequently present, and central neurofibrillary material may be seen in them.⁸³⁵ Glycogen may be present – a feature once thought to be restricted to Ewing's sarcoma (see later) (Fig. 37.31).⁸⁴⁰ The tumor cells contain neurosecretory granules and are usually positive for neuron-specific enolase, CD99, and PGP9.5.⁸⁴⁰ They show restricted expression of S100 protein and the various neuropeptides.

Extraskeletal Ewing's sarcoma has cells that often contain glycogen, but there are no neurosecretory granules or well-developed desmosomes.⁸⁴¹ Several histological variants have been reported in skeletal tumors.⁸⁴² The cells express CD99 in a characteristic membranous pattern^{831,843} but are negative for S100 protein and desmin.⁸⁴⁴ CD117 and FLI-1 are sometimes expressed.^{541,836} The presence of p16^{INK4a}

Figure 37.31 Malignant primitive neuroectodermal tumor (Ewing's sarcoma). This lesion was originally reported as Ewing's sarcoma, arising in the subcutis and involving the dermis of the back in a young person. (A) This is a densely cellular tumor composed of sheets of hyperchromatic cells with small amounts of cytoplasm. (B) Higher magnification, showing nuclear detail. Nuclei are relatively uniform, with dispersed chromatin. Small nucleoli can be seen in a number of the cells. (H&E) (C) Many of the cells contain glycogen. (PAS)

alteration is associated with a poorer prognosis.⁸⁴⁵ Merkel cell carcinomas are frequently positive for epithelial membrane antigen and CK20 – features not seen usually in MPNETs. Neuroblastomas are usually negative for CD99.⁸⁴⁶

A final diagnosis can usually be made only after the fluorescent *in situ* hybridization studies and immunohistochemistry results have been correlated.⁸⁴² Electron microscopy is now used infrequently.

Differential diagnosis

The differential diagnosis from Merkel cell carcinoma is discussed in the section devoted to that tumor. A minority of PNET lesions display intercellular rosette formation, but the fibrillary intercellular meshwork seen in some metastatic neuroblastomas is lacking in PNET. Nuclear pleomorphism or multinucleation are absent, in contrast to rhabdomyosarcomas. Neuroblastoma is uniformly negative for CD99 and reacts positively for MAP-2, in contrast to PNET, and rhabdomyo-

sarcoma differs by its consistent positivity for muscle-specific actin, with or without desmin expression.⁸⁴⁷ As noted previously, molecular analysis of PNET shows a t(11.22) translocation, whereas there are abnormalities of chromosomes 1 and 6 in Merkel cell carcinomas and of chromosomes 1, 11, and 17 in neuroblastomas. Allelic losses at 11p or t(1;13) or t(2;13) translocations are seen in rhabdomyosarcomas. Lymphomas can be excluded by their irregular nuclear contours, and tendency toward overlapping. CD45 expression is also a highly useful differentiating feature of lymphomas.⁸⁴⁸⁻⁸⁵¹ Other cutaneous tumors that can show an EWSR1 rearrangement include angiomatoid malignant fibrous histiocytoma and myoepithelioma of soft tissue.⁸⁵²

Reticulate telangiectatic erythema (sternal erythema)	1082				

INTRODUCTION

A renewed interest in vascular tumors was provoked by the emergence of AIDS-related Kaposi's sarcoma in the 1980s, and since then a number of new entities have been described.¹ Although many of these are rare, they may produce diagnostic dilemmas, several having many features in common with Kaposi's sarcoma.

The classification of the vascular tumors and ectasias is far from straightforward. First, there is difficulty in separating true neoplasms from reactive proliferations or developmental abnormalities. Second, some vascular lesions represent a dilatation of pre-existing vessels rather than a proliferation of new vessels. Finally, it may be difficult to distinguish between a lesion showing blood vessel differentiation and one with lymphatic features as, for example, in the case of Kaposi's sarcoma. Immunohistochemical, ultrastructural, and morphometric studies are helping to resolve some of these difficulties. An excellent, but selective, review of vascular tumors was published by Hunt and Santa Cruz in 2004.²

Vascular abnormalities of the skin are common. Approximately 50% of all neonates have some type of congenital vascular lesion.³ The classification adopted here is based on clinical classifications that were delineated comparatively recently.⁴ The distinction between malformations and vascular proliferations (tumors) has important clinical consequences. The distinction is more clear-cut clinically than it is on a shave or punch biopsy of skin. This is a dilemma that remains to be resolved (Fig. 38.1). Furthermore, some overlap does occur between vascular tumors and malformations.^{5,6} The following categories are considered:

- Hamartomas and malformations
- Vascular dilatations (telangiectases)
- Vascular proliferations
- Tumors with variable or uncertain behavior
- Malignant tumors
- Tumors with a significant vascular component.

Before doing so, a brief comment is made on tumor markers for vascular neoplasms. Although retained in this book, the first-generation vascular markers such as von Willebrand factor (factor VIII-related antigen) and the lectin *Ulex europaeus* are rarely used these days because of their nonspecificity or unreliable staining properties. They have largely been replaced by CD31 (platelet endothelial cell adhesion molecule-1) and CD34. CD31 does not usually stain

glomus tumors. It is negative also in some lymphatic lesions. On the other hand, CD34 also stains a number of soft tissue neoplasms. It also gives variable staining of lymphatic endothelium,⁷ but this has become less significant with the commercial availability of D2-40, an antibody to a sialoglycoprotein that reacts with an epitope on lymphatic endothelium.⁸ Vascular endothelial growth factor receptor type 3 was an initial marker, thought to be specific for lymphatic endothelium,⁹ that did not live up to its expectations. Anti-thrombomodulin antibody is another. It detects thrombomodulin, a cell surface glycoprotein that is present mainly on the luminal surface of endothelial cells of arteries, veins, capillaries, and lymphatics.⁷ A trial of the antibody revealed moderately intense staining in 89% of benign and malignant vascular tumors tested, whereas CD34 stained 98% of the same tumors.⁷ CD99, which has been said to be positive in 'epithelioid vascular neoplasms', has no place in the diagnosis of vascular neoplasms.¹⁰

HAMARTOMAS AND MALFORMATIONS

Hamartomas result from an error in embryological development and are present at birth. In the case of vascular hamartomas and malformations, they may become more obvious clinically some time after birth as a consequence of progressive ectasia. The constituent vessels may be capillaries, veins, arteries, lymphatics, or a combination of these vessels. Vascular malformations are associated with a range of dysmorphic syndromes, such as the Sturge-Weber syndrome and 'blue rubber bleb' nevus syndrome (see later).

ECCRINE ANGIOMATOUS HAMARTOMA

Eccrine angiomatous hamartoma is a rare malformation characterized by an increased number of small blood vessels, admixed with or adjacent to an increased number of eccrine glands (see p. 933) (Fig. 38.2). Rarely, it may have a segmental distribution and present as a capillary malformation (nevus flammeus).¹¹ There may also be an increase in mucin, fat, or nerve fibers.

Figure 38.1 This lesion illustrates some of the problems with nomenclature. It would have been called cavernous hemangioma in the past. It does not fit neatly into the venous malformations or other entities. (H&E)

Figure 38.2 Eccrine angiomatous hamartoma. Small blood vessels are admixed with eccrine glands. (H&E)

PHAKOMATOSIS PIGMENTOVASCULARIS

The term 'phakomatosis pigmentovascularis' refers to the coexistence of a vascular hamartoma, in the form of a capillary malformation (nevus flammeus), with a melanocytic lesion – usually a Mongolian spot or nevus spilus. Nevus anemicus, a functional abnormality of blood vessels (see p. 332), is often present. Five types of phakomatosis pigmentovascularis have been recognized based on the nature of the constituent abnormalities.¹² A new classification has recently been proposed (see p. 863). The condition is thought to result from an abnormality of neural crest development. The capillary malformation (nevus flammeus) is similar to the port wine stain (see later), although there may also be an increase in perivascular nerve fibers.¹² In type V, the only variant without a port wine stain, there are Mongolian spots associated with cutis marmorata telangiectatica congenita.¹³

CAPILLARY MALFORMATIONS (NEVUS FLAMMEUS)

Capillary malformation (nevus flammeus) is a generic term for a group of congenital vascular malformations that commonly involve the forehead, face, and neck of newborns. The term includes the 'port wine' stain, the 'salmon' patch, and the 'stork bite', the latter representing the combination of glabellar lesions with lesions on the nape of the neck. The lesions generally grow proportionately with the child's development, and there is usually **no** tendency for spontaneous involution, although the small 'salmon' patch usually fades early in life (see later).¹⁴ Happle questioned the use of the term capillary malformation for a specific cutaneous entity.¹⁵ He believes it should be used as an 'umbrella term' for at least nine different conditions.¹⁵

The term nevus flammeus has largely disappeared; it has been replaced by the terms *capillary malformation* or *port wine stain*.¹⁶ Capillary malformation is gaining a wider meaning and now includes the telangiectases in some reports.¹⁷ Capillary malformations are believed to represent an error in vascular development occurring during embryogenesis.

The port wine stain occurs in 0.3–0.5% of newborns.^{18–20} There is no sex predilection. Familial occurrence is rare.²¹ An acquired variant, which follows antecedent trauma, is said to occur very rarely.^{22–24} It may also follow oral isotretinoin.²⁵ Although any area may be affected, the lesion occurs most frequently on the face and neck. Single or multiple lesions may be present, and they are often sharply unilateral or segmental. Small or extensive areas of skin may be involved. At birth, the lesions are flat and light pink in color. Lesions may become darker and thickened with time, with undulation or cobblestoning.²⁶ This change is most common in facial lesions in the area of the second and third branches of the facial nerve.²⁷ An eczematous dermatitis develops within a port wine stain in a small number of cases;²⁸ this is considered an example of the Meyerson phenomenon in some reports.²⁹

The pulsed dye laser remains the standard of care for patients with port wine stains.^{20,30,31} Complete resolution is rarely seen,³² and up to 20% hardly lighten at all with laser therapy.³¹ Videomicroscopy shows when no further response can be expected. Other lasers have been tried,^{28,32,33} but the Nd:YAG laser, which is sometimes used for cases that do not respond, will result in scarring if fluences higher than the minimum purpura dose are used.³⁴ The further management of non-responding cases is beyond the scope of this book. This topic was discussed in two excellent reviews in 2007³¹ and 2008.²⁰

The 'salmon' patch (medial telangiectatic nevus) is a pink macular area present at birth in approximately 40% of the population. The nape of the neck, the eyelids, or the skin over the glabella may be involved.³⁵

In the majority of cases, the lesions fade in the first year of life.³⁵ There may be associated congenital abnormalities.^{36,37} In a small number of cases, the condition persists for life, particularly a lesion in the nuchal region.

Clinical syndromes associated with capillary malformations include the following:

- Sturge–Weber syndrome
- Klippel–Trenaunay syndrome
- Cobb's syndrome
- Capillary malformation–arteriovenous malformation (AVM) syndrome.

Sturge–Weber syndrome

The essential components of Sturge–Weber syndrome, also known as encephalotrigeminal angiomatosis, are as follows:

- A unilateral facial port wine stain that includes that area of skin supplied by the ophthalmic branch of the trigeminal nerve (forehead and upper eyelid)
- An ipsilateral vascular abnormality of the leptomeninges
- An ipsilateral vascular abnormality of the choroid of the eye.³⁸

The port wine stain may be associated with only one or other of the other components of the syndrome. It is present at birth. The syndrome is often associated with port wine stains on other areas of the body.³⁹ Sometimes facial lesions are bilateral. Such cases are associated with a higher incidence of eye and brain abnormalities.¹⁶ Glaucoma is the most common ophthalmologic abnormality found in this syndrome. Pyogenic granulomas and an arteriovenous malformation may develop in the lesions.⁴⁰

The pulsed dye laser is the treatment of choice for cutaneous lesions. The Sturge–Weber Foundation is an active support group for patients and families (<http://www.sturge-weber.org>).

Klippel–Trenaunay syndrome

The literature on Klippel–Trenaunay syndrome (OMIM 149000), also known as angio-osteohypertrophy, is somewhat confusing. However, the major elements are a port wine stain, usually on a limb, associated with varicose veins (present in 76–100% of cases), and limb overgrowth due to hypertrophy of bone and the associated soft tissues.⁴¹ The hypertrophy is usually localized, rather than generalized, hemi-hypertrophy – a feature associated with Wilms' tumor. Only one case of Wilms' tumor has been seen in this syndrome.⁴²

Since the original description, a number of other abnormalities have been described in conjunction with this syndrome. It should be distinguished from Parkes–Weber syndrome (OMIM 608355), in which there is significant arteriovenous (high-flow) shunting in the limb.^{39,43,44} Parkes–Weber syndrome is due to a mutation in the *RASA1* gene on chromosome 5q13.3.

The majority of cases of the Klippel–Trenaunay syndrome are sporadic, but familial cases have also been described.^{45,46} Capillary hemangiomas and venous malformations may be present.⁴⁷ The cutaneous capillary malformations may have a dermatomal distribution.⁴⁴ Lymphatic malformations are commonly present in this syndrome. They are usually present in patients with a 'geographic' cutaneous stain rather than a blotchy pattern.⁴⁸ Various techniques, such as magnetic resonance imaging and computed tomography, can be used to assess the extent of the disease.⁴⁹ There are many incomplete forms of this syndrome, and in one large series, a port wine stain was present in only 32% of cases.⁵⁰ Thrombosis may occur in the abnormal vascular channels, resulting in some cases in pulmonary emboli.⁴⁴

The genetic defect is currently unknown. A supernumerary ring chromosome 18 has been reported in this syndrome.³⁹

Cobb's syndrome

In Cobb's syndrome, there is a 'port wine' stain (or another vascular lesion) on the trunk or limb in a dermatomal distribution, corresponding to a segment of the spinal cord in which there is an arteriovenous or venous hemangioma.^{51,52}

Capillary malformation-AVM syndrome

The capillary malformation-AVM syndrome (OMIM 608354) was described in 2003.⁵³ The capillary malformations are small pink-red macules distributed widely over the skin, and the high-flow malformations may be in the skin or deeper bone or muscle. It shares phenotypic features with Parkes-Weber syndrome, which is not surprising because it is allelic to it, with mutations in the *RASA1* gene at 5q13.3.⁵⁴ It encodes the protein RAS p21. This genetic abnormality has also been found in capillary malformations without AVMs.⁵⁴

High-flow AVMs have been found in more than half of patients with the **PTEN hamartoma tumor syndrome**, the term now used for the allelic disorders Bannayan-Riley-Ruvalcaba syndrome (OMIM 153480) and Cowden's disease (OMIM 158350).⁵⁵ Intracranial venous anomalies are often present.⁵⁵ Excessive ectopic fat is often present in the cutaneous lesions.⁵⁵

Histopathology of capillary malformations

Initially, there is a barely detectable dilatation of the thin-walled vessels of the superficial vascular plexus. Progressive ectasia occurs, and there is obvious erythrocyte stasis (Fig. 38.3).⁵⁶ There is no significant increase in thickness or number of vessels with age in typical superficial lesions. In some cases, there is an underlying cavernous hemangioma, which may blend with the superficial lesion. Localized exaggeration of the vascular ectasia produces the roughened surface of the older lesions.^{27,57} In one case, these late changes were associated with epithelial and mesenchymal hamartomatous changes.⁵⁸ Secondary angiomatous lesions and pyogenic granulomas may occur within the main lesion.^{59,60}

One study has shown that the lesions are produced by dilatations of postcapillary venules of the superficial horizontal plexus, with no evidence of new vessel formation, although most authorities now believe that there is an increase in the number of vessels.¹⁷ The walls of the venules are thickened by basement membrane-like material and reticulin fibers.⁶¹ Progressive dilatation does not appear to be related to decreased fibronectin or type IV collagen in the vessel walls.⁶² A

Figure 38.3 Capillary malformation (nevus flammeus). Dilated, thin-walled vessels containing erythrocytes are noted in the superficial dermis. (H&E)

decreased nerve density has been demonstrated within affected areas, and it has been proposed that abnormal neural control of blood flow may be important in the pathogenesis of this lesion.⁶³ One immunohistochemical study showed that vessels were typical of capillaries, postcapillary venules, and small veins.⁶⁴ They are erythrocyte-type glucose transporter protein (GLUT-1) negative.

VENOUS MALFORMATIONS

Venous malformations are slow-flow vascular malformations that are present at birth. They are nonproliferating vascular birthmarks composed of anomalous ectatic venous channels.¹⁷ It has been known in the past as cavernous hemangioma. Superficial venous malformations are blue or purple papules or nodules, which may have a grouped configuration. Deeper lesions may impart little color to the skin.⁶⁵ Multiple lesions are present in the 'blue rubber bleb' nevus syndrome, Maffucci's syndrome, and the condition known as venous malformations with cutaneous and mucosal involvement (see later). Occasionally, venous malformations have a unilateral dermatomal (zosteriform) distribution.⁶⁶ This may represent a form of mosaicism of a more generalized process.⁶⁷ Most lesions arise sporadically, but familial cases with autosomal dominant inheritance occur. Unlike (capillary) hemangiomas, venous malformations lack a proliferative phase with thymidine incorporation and have little tendency to regress with time. Venous malformations are generally at a deeper level in the skin than hemangiomas. They may often involve muscle and be associated with painful thromboses. Coagulation disorders are often present in these patients as well;⁶⁸⁻⁷⁰ they may also complicate extensive venous/lymphatic malformations.⁷¹

The distinction between venous malformations and hemangiomas is not quite as clear-cut as the classification system of Mulliken *et al.* suggests.^{14,72} Dysmorphic syndromes occur with hemangiomas as well as with venous malformations; in some syndromes, such as Maffucci's syndrome, overlap lesions may occur. AVMs may also be present, leading to fast-flow lesions.⁷³ Vascular malformations that may also involve lymphatic channels are seen in **Proteus syndrome** (OMIM 176920), a rare, sporadic overgrowth disorder that is probably caused by a somatic mosaicism lethal in the nonmosaic state.^{74,75} The gene has been mapped to 10q23.31. In addition to the vascular/lymphatic malformations, there are soft tissue swellings (lipomas), macrodactyly, macrocephaly, and epidermal nevi.⁷⁵ The diagnostic criteria for this syndrome have been listed in a review.³⁹

Cutaneous vascular malformations are rare in **Gorham-Stout syndrome** (OMIM 123880), in which diffuse skeletal muscular (venous, capillary, and lymphatic) abnormalities lead to osteolysis (disappearing bone disease).^{39,76,77} A 2007 study suggested that the cutaneous lesions are lymphatic malformations.⁷⁸

Diffuse phlebectasia or **Bockenhimer syndrome** is characterized by a blue network of dilated veins.⁷⁹ This venous malformation involves more commonly upper, but also lower, extremities. It may involve muscles;⁷⁹ it is present at birth.³⁹

Cutaneous capillary-venous malformations, which are hyperkeratotic, are seen in a small percentage of persons with inherited cerebral capillary malformations (OMIM 116860).⁸⁰ The condition is due to mutations in the *CCM-1* gene that encodes for the KRIT1 protein. It is involved in the Ras signaling pathway and is important in cerebral and cutaneous vascular development.³⁹

There are several, somewhat overlapping syndromes in which multiple venous malformations form the major abnormality. They include the following:

- The 'blue rubber bleb' nevus syndrome
- Maffucci's syndrome
- Venous malformations with cutaneous and mucosal involvement.

Before they are discussed, mention is made of the classification used for GLUT-1-negative congenital vascular malformations of skin and soft tissue in a paper from Amsterdam.⁸¹ It forms the likely basis for future classifications of these lesions:

- Venous vascular malformation (veins of variable size, often with thick walls)
- Lymphatic malformations (mixed lesions with a substantial component of dilated thin-walled lymphatic channels and likely to increase in number with the advent of lymphatic markers)⁸²
- Deep arteriovenous malformations (tortuous arteries and veins often with fibrointimal thickening)
- Superficial arteriovenous malformation/acral arteriovenous tumor (localized nodular tumor of thick-walled arteries and veins of the skin and subcutis).

This latter category is discussed in this chapter as arteriovenous hemangioma (see p. 1086).

‘Blue rubber bleb’ nevus syndrome

The ‘blue rubber bleb’ nevus syndrome (OMIM 112200) was first named by Bean.⁸³ It is a rare disorder, characterized by multiple compressible blue rubbery venous malformations of the skin and of the gastrointestinal tract and occasionally other organs.^{84–89} Cortical blindness was present in one case.⁹⁰ Sinus pericranii is a rare association.⁹¹ The skin lesions may be present at birth or develop in childhood. They do not regress. Some, but not all, are characteristically painful or tender on palpation. There may be associated hyperhidrosis in the region of the tumors.⁹² Iron-deficiency anemia sometimes results from gastrointestinal hemorrhage.⁹³ Most cases are sporadic, but there is also evidence for an autosomal dominant mode of inheritance.⁹³ In one family, only males were affected.⁹⁴ Happle described cases with mosaic involvement by blue rubber bleb nevi superimposed upon a conventional, nonsegmental phenotype, suggesting type 2 mosaicism.⁹⁵

The cutaneous lesions are composed of irregular cavernous channels in the deep dermis and subcutis. There is smooth muscle in the vessel walls (Fig. 38.4). In some cases, vessels may be intimately related to dermal sweat glands.⁹² They represent true venous malformations and not ‘cavernous hemangiomas’ as labeled in the past. In one case, smaller lesional blood vessels expressed c-kit and MIB-1.⁹⁶

Figure 38.4 Blue rubber bleb nevus. There are large, dilated vessels lined by flat endothelium. Smooth muscle is present in vessel walls. (H&E)

Destructive modalities, including carbon dioxide laser, sclerotherapy, and surgical excision, have been used to treat cutaneous lesions.³⁹

Dermoscopic features of blue rubber bleb nevi include superficial, light red arborizing veins or vascular dilatation, maculae with undefined borders (palms and soles), and red-purple nodules with lacunae divided by white linear structures.⁹⁷

Maffucci's syndrome

Maffucci's syndrome is characterized by multiple vascular tumors of the skin and subcutis associated with multiple enchondromas of bone (OMIM 166000), particularly the long bones. The vascular tumors are usually venous malformations, but capillary hemangiomas, phlebectasias (dilated venules and veins), and lymphangiomas also occur. Spindle cell hemangioma (formerly called hemangioendothelioma) is also associated with this syndrome. Phlebolith-like bodies may develop in vascular channels. In two cases, only lymphangiomas were present.⁹⁸ The vascular tumors may be present at birth, but most appear during early childhood; they do not regress.^{99,100} Mucous membrane and visceral hemangiomas have also been reported.¹⁰⁰ There have been associations with other tumors and conditions, with recent reports of meningioma and pituitary adenoma¹⁰¹ and hyperparathyroidism with multinodular goiter.¹⁰²

Enchondromatosis results in variable shortening and deformity of the extremities. Skeletal lesions are predominantly unilateral in approximately half the reported cases.¹⁰⁰ There is no anatomical relationship between the osseous and vascular components.

There is probably an equal sex incidence and no familial grouping of cases.¹⁰⁰ Chondrosarcomas develop in approximately 15–30% or more of cases, and other cancers have also been reported.^{100,103} These associated tumors were reviewed in 2005.¹⁰⁴ The condition appears to be a generalized disorder of mesenchymal tissues.¹⁰⁵

Both Maffucci's syndrome and Ollier's disease (in which intraosseous enchondromas develop in proximity to growth plate cartilage) have been associated with mutations in the isocitrate dehydrogenase genes 1 and 2 (*IDH1* and *IDH2*, respectively), probably representing postzygotic events in these patients.¹⁰⁶ In Maffucci's syndrome, these mutations are found in both enchondromas and spindle cell hemangiomas.¹⁰⁷ A metabolic product associated with this mutation, 2-hydroxyglutarate (2HG), can be detected from central vascular and cartilaginous tumors of these and nonsyndromal patients.¹⁰⁶ Immunostaining for mutant *IDH1* R132H protein showed evidence suggesting tumoral and somatic mosaicism.¹⁰⁷

Venous malformations with cutaneous and mucosal involvement

This disorder (VMCM; OMIM 600195) is a rare condition that was described by Boon *et al.* in 1994.¹⁰⁸ It is characterized by ‘slow-flow’ venous malformations of the skin and oral mucosa.¹⁰⁹ In the original family, a few lesions were present at birth, but most appeared by puberty. It was not associated with gastrointestinal bleeding. It is caused by an activating mutation in the receptor tyrosine kinase (*TIE2/TEK*) gene on chromosome 9p21.¹⁰⁸ Another condition, known as **cerebral cavernous malformation** (CCM1; OMIM 604214), can also present with diffuse cutaneous vascular lesions having microscopic features of cavernous hemangiomas; this disorder has mutations of the krev interaction-trapped (*KRIT1*) gene.¹¹⁰

Histopathology of venous malformations

The malformations may be found at any level of the skin, but there is a tendency for them to occur in the deep dermis and subcutis. They

Figure 38.5 Venous malformation. There are dilated vascular channels in the deep dermis and subcutis. One of the channels contains a thrombus. (H&E)

consist of large dilated vascular channels lined by flat endothelium (Fig. 38.5). The walls of the vessels vary in thickness, but they are generally thin and fibrous. Some vessels may have smooth muscle in their walls and resemble dilated veins. Thrombosis may complicate these lesions. Calcification of the walls and phlebolith-like calcific bodies in the lumina may be found.

Electron microscopy

The endothelium is flattened and the basal lamina duplicated, with interspersed collagen fibrils.¹¹¹

CUTIS MARMORATA TELANGIECTATICA CONGENITA

Cutis marmorata telangiectatica congenita (CMTC; OMIM 219250), also known as congenital generalized phlebectasia, is a rare sporadic condition, although more than 300 cases have now been reported.¹¹² It is characterized by a persistent patterning of the skin by a reticulate network of dark violet-blue vessels (cutis marmorata), spider nevus-like telangiectases, and venous abnormalities variously described as phlebectasia, venous lakes, or venous hemangiomas.^{113–118} Lesions are usually located on the trunk or extremities, where they may be localized or generalized. They are often unilateral and have a mosaic pattern.^{119,120} The skin changes appear in the neonatal period, and in many cases they have a tendency to improve with time, often in the first 2 years.^{121,122} Lesions sometimes persist, but there are no features predictive of this outcome.¹²² In addition to cutaneous atrophy and ulceration or hypertrophy of the involved tissues, a range of other associated vascular and skeletal abnormalities has been described.^{115,123–129} Hypospadias has been present in several cases.¹³⁰ There is no involvement of internal organs by the vascular abnormalities.¹¹³ A resemblance between CMTC and neonatal lupus erythematosus has been described on a number of occasions.¹³¹

Widespread CMTC can also be seen in the Adams–Oliver syndrome (OMIM 100300). The coexistence of CMTC and extensive, large Mongolian spots has been classified as **type V phacomatosis pigmentovascularis**.^{13,112} The syndrome characterized by macrocephaly and CMTC (OMIM 602501) is now regarded as a type of capillary malformation and not related to CMTC.¹³² The name macrocephaly–capillary malformation has been suggested.¹³³

The etiology is uncertain. The condition may be a genodermatosis with autosomal dominant inheritance and reduced penetrance of the

gene. It has been suggested that it may represent a functional disturbance resulting from reduced α -adrenergic innervation of cutaneous terminal vessels.¹³⁴ A translocation was present in one case.¹³²

Histopathology

Various changes, including dilated capillaries and veins in the dermis and subcutis, have been described in this condition.^{113,135} A review of all cases of CMTC in the English-language literature found that the most common finding was dilatation of capillaries and veins in the dermis.¹³⁶ In two cases, and in the additional case reported, there was a proliferation of vascular channels. The implications of this proliferation on the course of the disease were not clear.¹³⁶ Focal acantholytic dyskeratosis has been reported as an incidental, but closely associated, abnormality in one patient.¹³⁷

GLOMULOVENOUS MALFORMATION

The glomulovenous malformation (GVM; OMIM 138000) was known in the past as a glomangioma and regarded as a variant of glomus tumor.^{138–145} Clinically, GVMs may simulate a venous malformation, but they are histologically distinct.¹⁴⁶ They accounted for 5% of venous anomalies in one vascular unit.¹⁴⁷ A majority of cases are familial with autosomal dominant inheritance, but a significant number are sporadic. Because relatives may have inconspicuous lesions, they may be missed. Familial GVM is due to a mutation in the *glomulin* gene on chromosome 1p21–p22.^{148,149} Numerous mutations have been described; they appear to be loss-of-function mutations.^{109,150}

Typically, GVMs are blue or violaceous lesions that may occur at any site or, rarely, the mucosa. They mostly occur on the extremities, but some occur on the trunk.^{147,151} Facial lesions are rare.^{152,153} GVMs are usually solitary, but multiple lesions are not uncommon. Lesions limited to one side of the body have been reported.¹⁵⁴ They may have a segmental distribution reflecting mosaicism.¹⁵⁵ They usually exhibit so-called ‘type 2 mosaicism’, which is characterized by conspicuous lesions locally superimposed on ‘milder’, disseminated lesions.^{156,157} Clinically, the lesions may be macular, nodular, or thickened, sometimes disfiguring plaques.¹⁰⁹ In this latter group are the congenital, disseminated, plaque-type variants that are often mistaken for venous malformations.^{158,159} They may extend deeply and involve muscle.¹⁴⁶ Smaller lesions may have hypertrichosis.¹⁶⁰ A case that clinically mimicked granuloma annulare has been reported.¹⁶¹ They are usually painless, unless palpated.

The GVM presents at an earlier age and is less common than its histological simulant, the glomus tumor. Unlike blue rubber bleb nevus, which it may clinically resemble, there is no gastric involvement in GVM.¹⁶²

Surgical excision is usually used for isolated lesions, but vascular lasers and carbon dioxide lasers can be used if lesions are superficial. Sclerotherapy is another treatment option.¹⁶³ Large, disfiguring lesions remain difficult to treat.¹⁰⁹

Histopathology

GVMs have more prominent vessels and less conspicuous glomus cells than the glomus tumor proper. GVMs are poorly circumscribed and unencapsulated, and they consist of irregular ectatic vascular channels irregularly surrounded by small numbers of glomus cells (Fig. 38.6). Glomus cells may be so sparse that the lesions can be difficult to distinguish from conventional hemangiomas. *Glomangiomas* refers to diffuse angiomas with a histological excess of glomus cells.¹⁶⁴ The exact nosological position of the *glomangiomyoma* is unknown. Familial generalized variants have been described.¹⁶⁵ Their histology suggests a variant of GVM with smooth muscle

Figure 38.6 (A) Glomulovenous malformation. (B) Large vascular channels are surrounded by a few layers of glomus cells. (H&E)

cells in the wall.^{165–167} A variant derived from glomus tumors may also exist.

LYMPHANGIOMA (CYSTIC LYMPHATIC MALFORMATION)

The term ‘cystic lymphatic malformation’ has been suggested as a more appropriate designation than lymphangioma for localized malformations of lymphatics.¹⁶⁸ Most are present at birth or arise in infancy or early childhood.^{169,170} It has been suggested that lymphangiomas represent sequestered lymphatic vessels that have failed to link up with the rest of the lymphatic system or with the venous system during embryological development.^{171,172} Histologically identical lesions arising because of acquired obstruction of lymphatics, often in association with lymphedema, are classified as lymphangiectases (see p. 1082). There have been several attempts to classify lymphangiomas: the classification of Flanagan and Helwig¹⁶⁹ divided them into superficial and deep types. Lymphangiomatosis is an additional category. Mulliken and Young,⁷² who prefer the term ‘cystic lymphatic malformation’, subdivided them into microcystic (lymphangiomas, verrucous hemangiomas, and angiokeratoma circumscriptum) and macrocystic (cystic hygromas and cavernous lymphangiomas). Combined macrocystic and microcystic lesions may occur.

Superficial lymphangioma

The superficial lymphangioma is also known as superficial microcystic lymphatic malformation and lymphangioma circumscriptum. Although these lesions may occur on almost any part of the body, they are most common on the proximal parts of the limbs and in the limb girdle regions.^{170,173} It rarely involves the vulva.¹⁷⁴ Penile lesions are also rare.^{175–177} Both vulval and penile lesions may mimic venereal lesions. Secondary infection is a complication of lymphangioma of the penis and of other sites.¹⁷⁸ There are typically multiple scattered or grouped translucent vesicles and papulovesicles in an area of skin; single small lesions composed of a group of vessels also occur.^{170,179,180} The lesions have been likened to frogspawn. Secondary hemorrhage and thrombus formation in vesicles may produce red or purple coloration in the lesions. Some lesions have a warty appearance due to epidermal hyperplasia and hyperkeratosis.¹⁸¹ There may be an underlying deep lymphangioma or other abnormality of lymphatic drainage, resulting in lymphedema and enlargement of the limb.^{182,183} The underlying muscle is sometimes involved.¹⁸⁴ Most of the lesions are present at birth or develop in early infancy or childhood. Occasionally, the lesions appear first in adult life:¹⁸⁵ this is most common in the small localized form.¹⁷⁰ In the typical extensive lesion, the superficial vessels communicate through deep vessels with large closed lymphatic cisterns in the subcutaneous or deeper tissues;¹⁸⁶ the superficial ectatic lymphatic vessels appear to result from raised pressure in these cisterns.^{171,187} Magnetic resonance imaging has been used to demonstrate the full extent of these lesions.¹⁸⁸ This underlying abnormality may explain the tendency of the lesions to recur after superficial excision. Lesions may enlarge and spread with time, and they may persist indefinitely. The development of lymphangiosarcoma has been reported in an area of superficial lymphangioma treated with radiotherapy.¹⁸⁹ Squamous cell carcinoma may also develop in these lesions.¹⁹⁰

Treatment is usually by surgical excision, but nonsurgical techniques such as cryotherapy, carbon dioxide laser, electrodesiccation, and bleomycin have been used. Results with these nonsurgical therapies have not been satisfactory.^{174,179} OK-432, a new sclerosant, produced satisfactory results when used on an extensive lesion of the vulva that was inoperable.¹⁷⁴ Hypertonic saline sclerotherapy can also be used.¹⁸⁵ The pulsed dye laser has also given good results.¹⁹¹

Histopathology

The epidermis is elevated above the general level of the skin by solitary or grouped ectatic lymphatics located in the papillary dermis (Fig. 38.7). This accounts for the raised vesicles seen clinically. These channels abut closely on the overlying epidermis and are thin walled, consisting predominantly of an endothelial lining. The vessels may contain eosinophilic proteinaceous lymph or blood or thrombus and occasionally foamy histiocytes or multinucleate giant cells.¹⁷¹ Scattered lymphoid cells are sometimes seen in the dermis. There is atrophy of the epidermis directly over the vessels, with elongation of the rete ridges such that the vessels may appear to be intraepidermal, the picture resembling that of angiokeratoma. Deep irregular lymphatics are sometimes seen beneath the surface vessels in the dermis and subcutis, particularly in the extensive lesions.¹⁷¹ The presence of these subcutaneous lymphatic cisterns with small amounts of smooth muscle in the wall are features that distinguish superficial lymphangioma (lymphangioma circumscriptum) from acquired lymphangiectasia, in which they are absent. Both share saccular dilatation of the superficial lymphatic channels.¹⁹²

The channels are highlighted by the lymphatic endothelial marker D2-40. Even more reliable markers for lymphatic endothelium may be prospero-related homeobox-1 (Prox-1), a homeobox-containing nuclear transcription factor, and vascular endothelial growth factor receptor 3 (VEGFR3).¹⁹³

Figure 38.7 Superficial lymphangioma. There are dilated lymphatic channels in the upper dermis. (H&E)

Deep lymphangioma

Deep lymphangioma (macrocytic lymphatic malformation) includes the lesions known as lymphangioma cavernosum (cavernous lymphangioma) and cystic hygroma.¹⁶⁹ The term 'cystic hygroma' has generally been used for large deep lymphangiomas in the neck or axilla that consist of single or multiloculate fluid-filled cavities. Cystic hygromas of the posterior triangle of the neck are associated with hydrops fetalis and fetal death, as well as obstructed labor.¹⁹⁴ There is an association with the 45,XO karyotype (Turner's syndrome), other congenital malformation syndromes, and several varieties of chromosomal aneuploidy.¹⁹⁴ A coexisting capillary malformation (nevus flammeus) has been reported overlying a cystic hygroma.¹⁹⁵ It is thought that deep lymphangiomas represent failed connection between the jugular lymph sac and the internal jugular vein.^{172,194} There is no clear-cut distinction between other deep lymphangiomas and classic cystic hygromas,¹⁶⁹ and it has been suggested that the appearance of the tumor is determined by the site and nature of the tissues in which it arises.¹⁹⁶ Deep lymphangiomas present as soft swellings in the skin and subcutaneous tissues. Progressive extension into deeper structures, such as muscle, is said to be an unfavorable sign.¹⁶⁹ The overlying epidermis is normal except in cases in which there is an associated superficial lymphangioma. When cut across, these tumors vary from a spongy mass of small vascular spaces to large and 'multicystic'. Most are present at birth or arise in the first few years of life.^{169,196} Lymphangioma scroti is the term used for deep and cavernous lesions of the scrotum. The adjacent inner thighs are often involved as well.¹⁹⁷

Histopathology

The histological picture of these tumors is inconstant. There are irregular dilated lymphatic channels of variable size in the dermis, subcutis, and deeper tissues (Fig. 38.8). These structures vary from an endothelium-lined channel with no obvious supporting stroma to vessels with thick fibromuscular walls. The intervening dermis or subcutis may be unaltered, or there may be loose or compact fibrous stroma.¹⁶⁹ Blood may be present in some channels. In larger lesions, collections of lymphocytes are sometimes present in the stroma and cause the endothelium to bulge into the vascular lumen. Lymphatic channels can be confirmed using the D2-40 antibody.

Lymphangiomatosis

Lymphangiomatosis, a rare disorder occurring mainly in children, may have skin lesions, although it primarily involves bones, parenchy-

Figure 38.8 Deep lymphangioma. Irregular dilated lymphatic channels are present in the deep subcutis. (H&E)

mal organs, and soft tissue.^{198–200} The prognosis in this form is related to the extent of the disease. A variant limited to bone, soft tissue, and skin, and with a good prognosis, has been described.¹⁹⁸ A lesson from a recent case is that in patients with recurrent chylothorax of unknown origin, the possibility of disseminated lymphangiomatosis should be considered and the patient examined for possible cutaneous lesions.²⁰¹

A new form of generalized lymphatic anomaly has been named **kaposiform lymphangiomatosis**. Typically occurring in children, although an adult has presented with the disease,²⁰² it presents with cough, dyspnea and fever, bleeding episodes (manifesting as epistaxis, ecchymosis, or hemorrhagic effusion), and a discrete, soft, nontender subcutaneous mass often located on the flank, scapular, posterior neck, or anterior chest wall.²⁰³ Extrathoracic sites of involvement include bone, spleen, abdominal viscera, and peritoneum. Other cutaneous manifestations include edema, violaceous discoloration, and lymphatic blebs. A range of medical and surgical therapies has been employed, but in the series of Croteau *et al.*, 5-year survival was 51%, with overall survival of 34%.²⁰³ The 'kaposiform' designation refers to the histopathologic features that accompany the clinical findings.

Histopathology

In lymphangiomatosis involving skin, the dermis and subcutis are infiltrated by dilated lymphatic channels that dissect dermal collagen and surround pre-existing structures – a pattern seen in well-differentiated angiosarcoma. Vessels are lined by a single layer of flat endothelium that stains positively for factor VIII-related antigen, *Ulex europaeus*-1 antigen, and, variably, with CD31 and CD34.¹⁹⁸ Thrombomodulin is a more recent marker, which is said to be specific for lymphatic endothelium.²⁰⁴ Podoplanin, detected by the antibody D2-40, is now the most specific marker of lymphatic endothelium.

The microscopic features of kaposiform lymphangiomatosis, which thus far have been described only in pulmonary parenchyma and associated structures, include sheets of spindled lymphatic endothelial cells associated with malformed lymphatic channels. The cells are associated with erythrocytes and intracytoplasmic hemosiderin granules. The spindled cells have been immunopositive for D2-40²⁰³ and Prox-1.²⁰²

Differential diagnosis

The extracutaneous microscopic findings described to date for kaposiform lymphangiomatosis could be confused with those seen in cutaneous lesions of kaposiform hemangioendothelioma (see later), another condition associated with abnormal lymphatic channels and occasionally with lymphangiomatosis. However, in kaposiform hemangioendothelioma, the spindle cells are organized in rounded, confluent nodules, with glomeruloid foci and microthrombi, whereas in kaposiform lymphangiomatosis they are configured in a parallel manner as dispersed, poorly demarcated clusters or anastomosing strands and sheets.²⁰³

VERRUCOUS HEMANGIOMA

Verrucous hemangioma is a vascular malformation that appears to arise at birth or in childhood, and it enlarges and spreads in later life.²⁰⁵⁻²⁰⁷ Lesions occur predominantly on the legs and consist of bluish-red soft papules, plaques, and nodules that become wart-like as the patient ages or following trauma.²⁰⁸ Satellite nodules may develop. Lesions may measure up to 8 cm in diameter.²⁰⁹ Recurrence is frequent after removal of the lesions because of involvement of the deeper tissues. An eruptive form with multiple disseminated cutaneous lesions and a linear variant have also been described.^{210,211}

Histopathology

Fully evolved lesions consist of dermal and subcutaneous foci of small and large vessels, with overlying verrucous hyperplasia of the epidermis. There is irregular papillomatosis with acanthosis and hyperkeratosis (Fig. 38.9). Angiokeratomatous areas may be present; however, unlike angiokeratomas, which are ectasias of superficial vessels (see p. 1080), verrucous hemangiomas involve deeper levels.^{205,206} Verrucous hemangiomas have been included in some classifications with the microcystic lymphatic malformations.¹⁶⁸

Immunostaining shows focal GLUT-1 endothelial positivity.²⁰⁹ There is low-level MIB-1 reactivity.²⁰⁹ D2-40, a marker of lymphatic endothelium, is negative.²⁰⁹ In another study, smooth muscle actin stained pericytes of the microvessels, whose endothelial cells were CD34+.²¹²

Figure 38.9 Verrucous hemangioma. There are irregular acanthosis and dermal vessels of varying sizes. Some vessels appear to be encased by epidermis in the manner of angiokeratoma, but the deeper vascular component seen here is not identified in angiokeratoma. (H&E)

The tested verrucous hemangiomas were positive for WT-1 (predominantly in the pericyte layer), which is expressed by vascular tumors but not vascular malformations.²¹³ The endothelial cells expressed brachyury (a marker of primitive mesoderm), Oct-4 (an embryonic stem cell marker), and ACE, part of the renin-angiotensin system; this result suggests a primitive microvascular phenotype.²¹² There is also CD45 positivity in verrucous hemangioma, indicating the presence of mature myeloid cells.²¹²

On dermoscopy, verrucous hemangioma has an ‘alveolar’ appearance, with dark blue pigmentation and dark round lacunae at the lesional periphery, varying shades of blue, and a blue-white veil.²¹⁴

Differential diagnosis

Verrucous hemangioma and infantile hemangioma have similar microscopic features (this is particularly true of involuting infantile hemangioma) and similar immunohistochemical findings. However, HBZ, the marker for hemoglobin subunit zeta (expressed by the yolk sac in the first trimester placenta), is negative in verrucous hemangioma but positive in infantile hemangioma,²¹⁵ suggesting a different cellular origin for the two tumors.²¹²

CALIBER-PERSISTENT ARTERY

Chronic ulceration of the vermilion border of the lips is sometimes associated with the presence of an artery of abnormally large caliber running in a very superficial location beneath the squamous epithelium. These vessels have been called ‘caliber-persistent arteries’ because of the failure of normal narrowing of the lumen as the vessel approaches the mucosal surface.^{216,217} A similar lesion has occurred on the eyelid.²¹⁸ Some cases have been misdiagnosed clinically as squamous cell carcinoma.²¹⁹ The vessel may show fibroelastic intimal thickening.²²⁰ Multiple sections may be necessary to demonstrate the vessels.²¹⁶ Brisk hemorrhage may follow the inadvertent biopsy of such a lesion.²²¹ The diagnosis can be made by Doppler ultrasonography.²²²

VASCULAR DILATATIONS (TELANGIECTASES)

In this group, the vascular channels of which the lesion is composed are predominantly pre-existing blood vessels that have undergone dilatation.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

In hereditary hemorrhagic telangiectasia (HHT), also known as Osler-Rendu-Weber disease (OMIM 187300), multiple punctate telangiectases occur in the skin and mucous membranes. The respiratory tract, gastrointestinal tract, and urinary tract may be involved.⁸³ The nasal mucosa, lips, mouth, and face are frequently affected, and epistaxis is the most common presenting symptom. Although lesions may be present in childhood, they do not usually appear until puberty. The number and size of the lesions increase with advancing age and also with pregnancy. The lesions may clinically mimic the telangiectases seen in the CREST syndrome.²²³ Fibrovascular abnormalities of the liver, cerebral arteriovenous fistulae, and pulmonary arteriovenous fistulae are associated abnormalities.²²⁴⁻²²⁶ Alterations in circulating microRNAs (miRNAs), specifically miR-210, can be used as a biomarker of pulmonary arteriovenous malformation in patients with HHT.²²⁷ Vitiligo and autoimmune thyroiditis have been reported, but they may have been coincidental.²²⁸ Cerebral abscesses are occasionally a complication.²²⁹

The incidence of the disease is approximately 1–2/10,000.²³⁰ Inheritance is by an autosomal dominant trait. HHT is caused by mutations in either the endoglin (*ENG*) gene on chromosome 9q34 (HHT1) or the activin A receptor type II-like kinase-1 (*ACVRL1* or *ALK1*) gene on chromosome 12q13 (HHT2).^{14,230,231} Both are transmembrane receptors for transforming growth factor- β , which plays a significant role in angiogenesis. Mutations in the *SMAD4* gene can cause a syndrome consisting of both HHT and juvenile polyposis.²³⁰ This mutation can also occur in uncomplicated HHT. Two further loci linked to chromosome 5 (HHT3) and chromosome 7 (HHT4) have been detected.²³⁰ Hundreds of different mutations in *ENG* and *ALK1* have been reported, including the deletion of the entire *ALK1* gene.²³⁰ The pulsed dye laser has been used in the management of cutaneous lesions.²³²

Histopathology

Within the dermal papillae, dilated thin-walled vessels are lined by a single layer of endothelium. Ultrastructural studies have shown these to be venules.²³³ Abnormalities in the endothelial lining have also been reported.²³⁴

GENERALIZED ESSENTIAL TELANGIECTASIA

Telangiectatic macules and diffuse erythematous areas likewise composed of a fine meshwork of ectatic vessels are seen in this condition, which occurs most frequently in females, appearing in early childhood.²³⁵ Lesions appear first on the lower extremities and spread gradually to involve the trunk and arms.²³⁶ Its diagnosis depends on the exclusion of other primary and secondary telangiectasias.²³⁷ Gastrointestinal bleeding from an associated ‘watermelon’ stomach has been reported.²³⁸ Conjunctival involvement is rare.²³⁹

Histopathology

Thin-walled vascular channels are found in the upper dermis. They are produced by dilatation of postcapillary venules of the upper horizontal plexus (Fig. 38.10).⁶¹ Cutaneous collagenous vasculopathy, in which there is marked collagen deposition within the vascular walls of the postcapillary venules in the superficial dermis, can also clinically resemble generalized essential telangiectasia and may in fact be a variant of that disorder (see later).

Figure 38.10 Generalized essential telangiectasia. The upper dermis contains congested and dilated vessels. (H&E)

HEREDITARY BENIGN TELANGIECTASIA

Hereditary benign telangiectasia (OMIM 187260) is inherited as an autosomal dominant trait. The disorder has been mapped in one family to the *CMC1* locus on 5q14, but this gene has been specifically excluded in one large family.²⁴⁰ A nonhereditary variant has also been reported.²⁴¹ It is characterized by widespread cutaneous telangiectases, which commonly appear in childhood.²⁴² In some of the pedigrees, the telangiectases are limited to sun-exposed areas, but in others the lesions are widespread.²⁴⁰ They may be separate entities. Congenital lesions also occur.²⁴³ Many lesions on the face may resemble spider nevi. In one variant, the telangiectases are punctate and surrounded by an anemic halo; no unique microscopic changes are associated with this variant, which shows dilatation of the subpapillary venous plexus.^{244,245} The lesions are more prominent during pregnancy. No systemic vascular lesions are associated with this form of telangiectasia.^{246,247} The lesions are characterized by dilatation of the horizontal subpapillary venous plexus.²⁴³

UNILATERAL NEVOID TELANGIECTASIA

Unilateral nevroid telangiectasia is also known as unilateral dermatomal superficial telangiectasia. The telangiectases have a dermatomal distribution and particularly involve the trigeminal and the third and fourth cervical and adjacent dermatomes.²⁴⁸ The lesions may be present at birth,²⁴⁹ or they may be acquired at times of physiological or pathological estrogen excess, including puberty and pregnancy in females, and chronic liver disease.^{250,251} They have been reported to be superimposed on Bier spots, which are hypopigmented macules associated with anatomic or functional abnormalities of small cutaneous vessels (see p. 332).²⁵² The condition has been reported in association with metastatic carcinoid tumor²⁵³ and also in two males with hepatitis C but without evidence of cirrhosis or abnormal hormone levels.²⁵⁴ It has also developed in a young man after chemotherapy.²⁵⁵ Other recently described associations include neurological disorders (hypoesthesia over the cutaneous lesions, subcortical hamartomatous lesions, and demyelinated plaques),²⁵⁶ ipsilateral melorheostosis,²⁵⁷ and cirrhosis and stroke.²⁵⁸ Increased numbers of receptors for estrogen and progesterone have been reported in the lesional area compared to normal skin.²⁵⁹

Pulsed dye laser is a useful modality for treating this condition, although reversible pigmentary disturbances often occur in persons of color.²⁶⁰

ATAXIA–TELANGIECTASIA

Ataxia–telangiectasia (Louis–Bar syndrome; OMIM 208900) is an inherited, progressive neurological disorder resulting from cerebellar degeneration.²⁶¹ Cutaneous telangiectases are a constant but clinically unimportant part of this syndrome.^{262,263} Telangiectases appear in childhood in the bulbar conjunctiva and in the skin of the face, pinnae, neck, and limbs. They arise from the superficial vascular plexus. These changes are followed by progressive cerebellar ataxia from cerebellar cortical atrophy. Other skin changes have been described, including granulomas, segmental pigmentation, progeric changes, and seborrheic dermatitis.^{264–268} Cutaneous granulomas have been described in ataxia–telangiectasia on a number of occasions;²⁶⁹ in one study, it was proposed that immune dysregulation is at work in these patients, particularly related to a marked decrease to absence of B cells and naive T cells, with perhaps unopposed activity of γ/δ T cells or natural killer cells.²⁷⁰ Profound dysfunction of both cell-mediated and humoral immunity results in decreased resistance to viruses and recurrent sinus and pulmonary infections.²⁶¹ Thymic

aplasia or hypoplasia and a decrease in the lymphoid tissue in lymph nodes, spleen, and elsewhere are associated with deficiency of IgA, IgE, and IgG and with abnormal function of T lymphocytes. An increased sensitivity to ionizing radiation and a markedly increased risk of developing cancers, particularly lymphomas and leukemias, are other facets of this syndrome. Affected persons have a shortened life expectancy, with death usually occurring in the second or third decade of life.

Inheritance is autosomal recessive with variable penetrance. Mutations occur in the ataxia–telangiectasia mutated (*ATM*) gene on chromosome 11q22.3. ‘Homozygotes’ (strictly speaking, many are compound heterozygotes because each of their chromosomes 11 carries a different mutation) express the full syndrome. Heterozygotes have an elevated risk of cancer, especially female breast cancer; of ischemic heart disease; and of early mortality.²⁷¹ The *ATM* protein has several important roles. It may be associated with dysregulation of the immunoglobulin gene superfamily, and it has a role in signal transduction and cellular responses to DNA damage.³⁹ Accelerated telomere loss may be responsible for other manifestations.

‘SPIDER’ ANGIOMA

One or more ‘spider’ angiomas (nevi) are present in 10–15% of normal adults.⁸³ The face, neck, upper part of the trunk, and arms are the regions usually involved; it is very uncommon for lesions to occur below the level of the umbilicus. There is a higher incidence in pregnant women and in patients with chronic liver disease. Lesions may regress following pregnancy. In children, ‘spider’ nevi tend to arise on the hands and fingers.²⁷²

‘Spider’ angiomas consist of a central punctum within a generally circular area of erythema. Fine branching vessels or ‘legs’ radiate from the punctum.

Sclerotherapy is often used to treat these lesions.²⁷³

Histopathology

These lesions are rarely biopsied or excised. They consist of a central ascending spiral thick-walled arteriole that ends in a thin-walled ampulla just beneath the epidermis (Fig. 38.11). From the ampulla, thin-walled branching channels radiate peripherally in the papillary dermis. Glomus cells have been described in the wall of the central arteriole.⁸³

VENOUS LAKE

Venous lakes are common vascular ectasias. They appear as soft, dark-blue, often multiple, papules a few millimeters in diameter, which occur on the ears, face, lips, or neck of the elderly.^{274,275} Minor trauma to the lesions may produce persistent bleeding.

The lesions reported as capillary aneurysms probably represent venous lakes.²⁷⁶ The clinical similarity of these lesions to malignant melanomas has been highlighted, particularly if thrombosis of the vascular lumen occurs.

Many venous lakes are removed by punch or surgical excision. They may also be treated by cryosurgery and electrodesiccation. Lasers, particularly the pulsed dye laser, are also effective.²⁷⁷

Histopathology

Usually, only a single large dilated vascular channel is present, in the upper dermis (Fig. 38.12). It has a very thin fibrous wall and a flat endothelial lining. A thrombus is sometimes present in the lumen or part thereof. These lesions appear to represent a dilated segment of a vein or venule.²⁷⁴

Figure 38.11 ‘Spider’ angioma (nevus). A deep dermal vessel has given rise to a vertically oriented vessel leading into a superficial ampulla. There are thin-walled vessels in the upper dermis. (H&E)

Figure 38.12 Venous lake. There is a solitary large vascular channel in the upper dermis. (H&E)

ANGIOKERATOMA

The angiokeratoma is characterized by ectasia of superficial dermal blood vessels, with associated epidermal changes. Five clinical variants have been recognized: all have similar histopathological features.²⁷⁸ The variants are discussed here:

1. The *Mibelli type* develops in childhood and adolescence, with warty lesions over the bony prominences of the hands, feet, elbows, and knees.^{278,279} The term 'hyperkeratotic vascular stain' has been used for congenital lesions.²⁸⁰ It is more common in females, and it may be associated with pernio. A thrombosed solitary lesion may mimic malignant melanoma.²⁸¹ Laser treatment is a common method of treatment.²⁸⁰
2. The *Fordyce (scrotal) type* arises as early as the second and third decades, but it is seen most commonly in elderly men.^{83,282} The penis, upper part of the thighs, and lower part of the abdomen may also be involved.²⁸³ The lesions are single or multiple, red to black papules, occurring along the course of the superficial scrotal vessels. Scrotal angiokeratomas may be associated with varicoceles,²⁸⁴ inguinal hernias, an oral angiokeratoma,²⁸⁵ and thrombophlebitis.²⁸² Spontaneous regression has been reported following the surgical treatment of an associated varicocele.²⁸⁶ An equivalent lesion occurs on the vulva in young adult females. Increased venous pressure associated with pregnancy, vulval varicosities, or hemorrhoids has been implicated in the pathogenesis of the vulval lesions.²⁸⁷ An association with the contraceptive pill has also been suggested.²⁸⁸
3. *Solitary and multiple types* occur on any part of the body, but the lower extremities are most commonly affected. In one series, the lesions were solitary in 83% of cases and multiple in 17%.²⁷⁸ A zosteriform distribution has been described.²⁸⁹ Angiokeratomas have been reported in a patient with juvenile dermatomyositis.²⁹⁰ It was postulated that the lesions developed as a compensatory response to the obliterative angiopathy of the dermatomyositis. They have also been reported in association with cerebral cavernous malformations.⁸⁰
4. *Angiokeratoma circumscriptum* is the least common variant.²⁹¹ It consists either of a plaque composed of small discrete papules or of variable hyperkeratotic papules and nodules with a tendency to confluence.^{292,293} A linear lesion has been described.²⁹⁴ Lesions are almost always unilateral, and they occur predominantly on the leg, trunk, or arm. The neck and the penis are rare sites.^{294,295} Lesions develop in infancy or childhood, predominantly in females. It may be better classified as verrucous hemangioma, particularly in cases that have a deeper dermal hemangioma component.
5. *Angiokeratoma corporis diffusum* consists of multiple papules, frequently in clusters, and usually in a bathing-trunk distribution. Originally thought to be synonymous with Anderson–Fabry (Fabry) disease (OMIM 301500), it is now evident that this vascular lesion may occur in association with other enzyme disorders and also in people with normal enzyme activity (see p. 563).^{296–300} Anderson–Fabry disease is an X-linked recessive disorder characterized by a deficiency of the lysosomal enzyme α -galactosidase A and the accumulation of the neutral glycolipid ceramide trihexidose in lysosomes in many types of cell.³⁰¹ Homozygous male patients generally, but not always, develop the lesions of the disease.³⁰² The skin lesions are usually present by adult life; the changes are often absent or slight in childhood.³⁰³ An eruptive form is exceedingly rare.³⁰⁴ Females with the genetic abnormality may also develop the lesion, but this occurs in less than 25% of cases.³⁰³ Other enzyme deficiencies associated with angiokeratoma corporis diffusum include α -l-fucosidase deficiency

Figure 38.13 Angiokeratoma. The elongated rete ridges partly surround the vascular channels in the papillary dermis. (H&E)

(fucosidosis; OMIM 230000), β -galactosidase deficiency (OMIM 256540), α -N-acetylgalactosaminidase deficiency (Kanzaki disease; OMIM 609242),^{305,306} β -mannosidase deficiency (OMIM 248510),^{307,308} aspartylglucosaminidase deficiency (OMIM 208400),³⁰⁹ and neuraminidase deficiency (OMIM 256550).^{310–312} A dominantly inherited form, associated with arteriovenous fistulae but no metabolic disorder, has been reported.³¹³

Treatment depends on the number, size, and extent of the lesions. Surgical excision is an option for smaller lesions. Cryotherapy and electrocautery can be used, but recurrence and/or scarring may occur with these two procedures. Laser therapy with CO₂, argon, or pulsed dye laser may also be used.

Histopathology

In angiokeratomas, there is marked dilatation of papillary dermal vessels to form large cavernous channels. There is associated irregular acanthosis of the epidermis with elongation of the rete ridges that partially or completely enclose the vascular channels (Fig. 38.13). A collarette may be formed at the margins of the lesions, and there may be thrombosis of the vessels. The surface epidermis may show varying degrees of hyperkeratosis. The occurrence of a deep dermal hemangioma has been reported in association with angiokeratoma circumscriptum.^{292,314} This combination may therefore represent a verrucous hemangioma. In patients with Anderson–Fabry disease, there is vacuolation of smooth muscle in arterioles and arteries and in the arrectores pilorum. Frozen sections of lesions may show periodic acid–Schiff (PAS)-positive and Sudan black-positive granules in endothelial cells, pericytes, arrectores pilorum, and eccrine sweat glands. The vessels do not usually express CD34.³¹⁴

Dermoscopy is helpful in improving the diagnostic accuracy of solitary angiokeratomas. Red lacunae intermingled with a whitish veil have been found.³¹⁵ The presence of dark lacunae on dermoscopy has a specificity of 99%.³¹⁶

Electron microscopy

Examination of lesions or of normal skin from patients with Anderson–Fabry disease shows electron-dense lipid bodies in the cytoplasm; they are either membrane bound or free in the endothelial cells, pericytes, smooth muscle cells, and fibroblasts. These bodies may show a characteristic lamellar pattern. They are not seen in the other types of angiokeratoma or in the lesions in cases of angiokeratoma corporis diffusum with normal enzyme activities.²⁹⁶

The ultrastructure of the vessels in scrotal angiokeratomas and in Anderson–Fabry disease is similar to that of the small valve-containing collecting veins at the junction of the dermis and subcutaneous fat.⁶¹ The possible role of raised intravenous pressure in the formation of scrotal and vulval angiokeratomas has been mentioned. It has been suggested that the lesions in Anderson–Fabry disease may follow weakening of vessel walls and subsequent dilatation, the result of lysosomal storage of lipid and consequent cellular damage.³¹⁷

Differential diagnosis

Another disorder, termed **acral pseudolymphomatous angiokeratoma of children** (APACHE), consists of papules over acral surfaces, and despite the name it also occurs in adults.³¹⁸ Although the lesions clinically resemble angiokeratomas, they are quite different microscopically, displaying a predominantly lymphocytic, band-like infiltrate in the upper dermis (but also including macrophages, plasma cells, and eosinophils), associated with thick-walled vessels with plump endothelium. The vessels have been both CD34 and D2-40 positive; the lymphocytic infiltrate is composed of B and T cells (with B cells often predominating in children and T cells in adults), without evidence of clonality.^{318–320} The lesions have much in common with angiolymphoid hyperplasia with eosinophilia, and in fact the designation ‘papular angiolymphoid hyperplasia’ has been suggested for these lesions by Hagari *et al.*³²¹

MISCELLANEOUS TELANGIECTASES

Numerous skin disorders are associated with telangiectases. These include such disparate conditions as collagen vascular disease, cutaneous mastocytosis (OMIM 248910), and chronic graft-versus-host disease. Telangiectases may appear following trauma, including repetitive injury from the use of a keyboard (‘computer palms’),³²² or be associated with skin damage due to solar and other forms of radiation (Fig. 38.14).

Several syndromes are associated with cutaneous telangiectases, such as Cockayne’s syndrome (OMIM 216400), Bloom’s syndrome (congenital telangiectatic erythema; OMIM 210900), and Rothmund–Thomson syndrome (poikiloderma congenitale; OMIM 268400).²⁶² Bloom’s syndrome is a rare autosomal recessive genodermatosis consisting of photosensitivity, telangiectases, growth retardation, and an increased incidence of malignancies.³²³ The defect has been mapped to chromosome 15q26.1.

Figure 38.14 Secondary telangiectasia occurring in sun-damaged skin. (H&E)

An apparently unique case, characterized by generalized telangiectasias with marked collagen deposition around the basal lamina of the vessels resembling amyloid (Fig. 38.15), was reported as **cutaneous collagenous vasculopathy**.^{324,325} Microscopically, this material has a hyalinized appearance and is PAS, trichrome, and colloidal iron positive, staining for collagen IV, fibronectin, and laminin but not for actin. A case with multiple intravascular fibrin thrombi has been reported.³²⁶ Ultrastructural studies have shown that the material consists of fibrils of interstitial collagen embedded in medium electron-dense granular material.³²⁷ Luse bodies (long spacing collagen) were found by the authors of the original case report. Although described as a ‘rare’ condition, 13 papers have been published regarding this disorder since 2010 (to date), and the editor has personally seen at least six cases since the original report by Salama and Rosenthal.^{328–330} Therefore, this is likely to be a not-uncommon but heretofore under-reported condition that manifests clinically as generalized essential telangiectasia.

The nature of the two cases with dome-shaped papules resembling hemangiomas that eventually resolved leaving pigmented areas is unknown.³³¹ The eruptions were recurrent, but they took longer to heal than the lesions of eruptive pseudoangiomatosis (see p. 1095). The lesions were regarded as being telangiectatic in type.³³¹

Figure 38.15 Cutaneous collagenous vasculopathy. (A) Marked collagen deposition is present around the basal lamina of dermal vessels. (B) The material has some resemblance to amyloid, but it stains for collagen IV, fibronectin, and laminin. The clinical presentation in this case was similar to generalized essential telangiectasia. (H&E)

DRUG-INDUCED TELANGIECTASIA

Iatrogenic telangiectases have been produced by lithium, isotretinoin, and interferon- α (IFN- α). Photodistributed telangiectases have been reported following the use of cefotaxime (a cephalosporin); the calcium channel blockers nifedipine, felodipine, and amlodipine;³³²⁻³³⁶ and the serotonin-norepinephrine reuptake inhibitor venlafaxine.³³⁷

RETICULATE TELANGIECTATIC ERYTHEMA (STERNAL ERYTHEMA)

Reticulate telangiectatic erythema is an asymptomatic telangiectatic and erythematous plaque that develops some time after the implantation of a device, usually a pacemaker or cardiac defibrillator.^{338,339} It has also been reported overlying a hip prosthesis.³⁴⁰ The cases reported as sternal erythema, a distinctive thoracic surgical wound eruption that developed after coronary bypass grafting,³⁴¹ appear to be a related entity.³⁴² So too are the erythematous patches, sometimes quite large, that develop on the breast following a surgical procedure. Patch testing in all cases has been negative, but it is still postulated that the lesion represents a reaction to implanted hardware, which may simply be sternal wires in the cases overlying bypass surgery wounds. It has also been suggested that it may be an anatomic variant of costal fringe (see later).

Histopathology

All cases have shown variable but usually mild epidermal atrophy and capillary telangiectasia in the upper dermis. The infiltrate, which is perivascular and lymphocytic, is usually sparse, but it was a little heavier in the case overlying the hip prosthesis.³⁴⁰

COSTAL FRINGE

Costal fringe is an acquired lesion in elderly men and, less frequently, elderly women. It consists of a band-like pattern of telangiectases across the anterior aspect of the thorax, usually near the costal margin. It is uncommon in young adults.³⁴³ The telangiectases represent dilated postcapillary venules of the superficial vascular plexus.³⁴⁴

LYMPHANGIECTASES

Lesions that are clinically and histologically similar to superficial lymphangiomas (cystic lymphatic malformations) may develop in areas of skin affected by obstruction or destruction of the lymphatic drainage.^{181,345} The interference with the lymphatics may result from radiotherapy or surgery,³⁴⁶⁻³⁴⁸ and it has been described in the chest and arm following radical mastectomy and radiotherapy,³⁴⁹⁻³⁵² in the penis and scrotum following surgery for a sacrococcygeal tumor,³⁵³ and on the vulva and the thigh following surgery and radiotherapy for carcinoma of the cervix.³⁵⁴⁻³⁵⁸ Chylous reflux may rarely present with milia-like lymphangiectasia of the thighs³⁵⁹ or scrotum.³⁶⁰ It has also occurred following female genital mutilation performed as a cultural practice.³⁶¹

Lymphangiectasia has also developed on the abdomen in a patient with cirrhotic ascites and previous liver transplantation. Peritoneal mesothelial cells refluxed into the cutaneous lesions.³⁶²

Cutaneous lymphangiectases have also been reported in association with severe photoaging and topical corticosteroid application.³⁶³ Facial lymphangiectases are a rare complication of porphyria.³⁶⁴

Lymphedema, a chronic condition characterized by swelling of one or more limbs or other parts of the body, is due to a defect in lymph transport. It contributes to local infections, such as cellulitis in the affected limb.^{365,366} Severe lymphedema of the extremities, genitalia,

and face is associated with intestinal lymphangiectasia in Hennekam syndrome (OMIM 235510).³⁶⁷ Lymphangiectasia is a feature leading to the lymphedema. Learning disability is also a feature of this syndrome.

VASCULAR PROLIFERATIONS (HYPERPLASIAS AND BENIGN NEOPLASMS)

This group of vascular tumors includes a variety of lesions in which there is a hyperplasia or a benign neoplastic proliferation of blood vessels of different types.³⁶⁸

INFANTILE HEMANGIOMA

Infantile hemangioma (hemangioma of infancy), a benign proliferation of blood vessels, has also been called in the past 'strawberry' nevus, infantile capillary hemangioma, and benign infantile hemangioendothelioma.^{369,370} They are the most common tumors of infancy, with an incidence in the newborn population of approximately 2%. They are especially common among infants born prematurely.^{371,372} They can affect up to 10% of white children within the first year of life.²⁰ A systematic review of the medical literature led the authors to conclude that 10% was probably an overestimation and that the incidence was closer to 4 or 5%.³⁷³

In most series, there is a female preponderance.^{374,375} Familial cases are rare.³⁷⁶ Some of these cases (OMIM 602089) have autosomal dominant inheritance with genes mapped to the 5q region. One or more lesions may be present on any part of the body, but the head, neck, and trunk are the most commonly affected sites.³⁷⁷ In a series from New York University, 379 hemangiomas from 316 patients were studied. Of these hemangiomas, 57% occurred on the head and neck, 19% on the trunk, 14% on the extremities, and nearly 10% on the perineum.³⁷⁸ Of the 216 hemangiomas on the head and neck, 190 were focal and 26 were segmental. The parotid gland and overlying skin may be involved, this being the most common tumor of the parotid gland in children.³⁷⁹ Lesions are often not visible at birth but appear in the first few weeks of life. Rarely, a faint erythematous macule or an area of pallor with telangiectasia is present at birth.³⁸⁰ The lesions evolve and enlarge over a period of months to become raised and bright red in color, with a smooth or irregular surface. Sometimes they mimic a bruise.³⁸¹ A small number are abortive and show minimal growth.³⁸²

Other hemangiomas that are rapidly involuting or non-involuting occur.^{383,384} Interestingly, these lesions are usually both GLUT-1 negative.^{383,385} The rapidly involuting congenital hemangiomas (RICH) may present with thrombocytopenia, low fibrinogen, and elevated fibrin degradation products. It is transient and dissimilar to the Kasabach-Merritt phenomenon.³⁸⁶ RICHs are fully developed at birth and involute rapidly during the first month of life. They are sometimes quite large and exophytic. They seldom require treatment.³⁸⁶ The non-involuting capillary hemangiomas (NICH) grow proportionately with the child.³⁸³ The vessel walls in these tumors are often thicker, and the endothelium may have a hobnail appearance.³⁸⁷

Most infantile hemangiomas have reached maximum size by the age of 3–6 months.^{377,380} A brief plateau period then ensues. Total or partial regression then occurs in the majority of lesions and is usually maximal by 5–7 years of age.^{375,377} This regression appears to be mediated by apoptosis accompanied by reduced proliferation of cells.³⁸⁸ Most cases therefore require no surgical intervention,^{380,389} although newer laser techniques and even cryosurgery are being used with success.^{380,389,390} Pulsed dye laser treatment should be confined to superficial, ulcerating variants and to residual telangiectasia of involuted hemangiomas only.²⁰ It has been suggested that embolization is an important mechanism in the laser destruction of cutaneous lesions.³⁹¹ Periorbital lesions

may warrant active therapy because of the association of visual complications.^{380,392-394} Complete involution is less likely to occur where there is a deep cavernous component or more complex vascular malformation.³⁹⁵⁻³⁹⁷

Ulceration, which is the most common complication of hemangiomas, occurs in 5–21% of cases. Treatment is mandatory because significant pain, the potential for bleeding and infection, and the increased risk of scarring exist.³⁷⁸ Treatment of such cases usually involves a combination of local wound care, barrier creams, topical antibiotics, and systemic or intralesional corticosteroids.^{378,398} Pulsed dye laser has also been used (discussed previously).

A locus for an autosomal dominant predisposition to hemangiomas has been identified on chromosome 5q. A similar locus may be involved in the formation of sporadic hemangiomas.^{399,400} Molecular studies of vascular tumors have found abnormalities of different tumor suppressor genes located on various chromosomes. Multiple hemangiomas were reported in a patient with a t(3q;4p) translocation.⁴⁰¹

It has been suggested that the incidence of infantile hemangiomas is increased following chorionic villus sampling during pregnancy.⁴⁰² Other ischemic placental injuries are also associated with an increase in infantile hemangiomas. In a comparative study of 13 neonates who developed hemangiomas with 13 who did not, there were major differences in placental morphology in the two groups. Gross lesions with disturbances of the uteroplacental circulation were found in all 13 cases with infantile hemangiomas, whereas only 3 cases in the control group had any placental changes at all, and in 2 cases they were mild.⁴⁰³ Interestingly, these hemangiomas share a phenotype with the placental microvasculature,^{404,405} but a comparatively recent study has shown that the endothelial cells originate from the child and not from the mother.⁴⁰⁶

Multiple disseminated cutaneous hemangiomas are sometimes associated with multiple visceral hemangiomas (diffuse neonatal hemangiomatosis). This is usually a fatal disorder (see later). *Solitary, segmental hemangiomas* of the skin can also be associated with visceral hemangiomatosis.^{407,408} They are frequently associated with other developmental abnormalities as well.⁴⁰⁹⁻⁴¹² Ulceration is more likely in these segmental (facial) lesions compared to the focal, tumor-like type.⁴¹³ Systemic corticosteroids prevent the further growth of these lesions and reduce the pain.⁴¹⁴ Care must be exercised with corticosteroids in infants because complications of therapy are common.⁴¹⁵

The simultaneous occurrence of infantile hemangiomas and congenital melanocytic nevi has been reported. The intimate relationship of some of these lesions led the authors to speculate that their concurrence was not coincidental.⁴¹⁶ Congenital pseudoclubbing of the fingernail may accompany subungual hemangioma.⁴¹⁷

Other work has shown that the endothelial cells of these hemangiomas have the cell morphology and protein expression of embryonic endothelial cells, indicating a dysfunction in maturation of the endothelial cells in these lesions.⁴¹⁸ Another study has shown that the endothelial cells of these hemangiomas have high levels of erythrocyte-type GLUT-1, but this is not found in vascular malformations.⁴¹⁹ Cellular adhesion molecules are also involved in the formation and maturation of hemangiomas. ICAM-3 appears to play a role in the early stages of vessel formation.⁴²⁰ The finding of hypoxia inducible factor 2 α (HIF-2 α) in the nuclei of hemangiomas is interesting in view of the relationship of this tumor to hypoxic events.⁴²¹ This results in downstream overexpression of VEGF.⁴²¹ Recently, it has been shown that the pattern of Notch gene expression (the Notch family of cell signaling molecules plays a role in embryonic vascular development and postnatal tumor angiogenesis) reflects the progression from immature cells to endothelial differentiation in the development and involution of infantile hemangiomas.⁴²² COSMC, described as a 'molecular chaperone' of T-synthase, is said to play a role in blood vessel formation; it appears to regulate VEGF-induced phosphorylation of VEGFR2 and therefore regulates VEGFR2 signaling in endothelial cells. It has been

proposed that dysregulation of COSMC expression may be involved in the pathogenesis of hemangiomas.⁴²³

The finding that the endothelial cells in this tumor are clonal has major implications for our understanding of this lesion.⁴²⁴ It supports their separation from venous malformations.⁴²⁵ This finding is consistent with the possibility that these tumors are caused by somatic mutations in one or more genes regulating endothelial cell proliferation.⁴²⁴

The treatment of infantile hemangiomas was discussed, in part, previously. Newer therapies being tried for superficial lesions include imiquimod 5% cream.⁴²⁶⁻⁴²⁸ Misdiagnosis of vascular lesions is still a problem; it can lead to inappropriate treatment.^{429,430}

Diffuse neonatal hemangiomatosis

Multiple cutaneous hemangiomas may occur with or without disseminated visceral hemangiomas.⁴³¹ Segmental hemangiomas often have similar visceral associations. The cutaneous lesions are capillary hemangiomas, which are present at birth or appear in infancy. Sometimes they have been called miliary hemangiomatosis.⁴³² In cases with visceral involvement, any organ may be affected. Visceral involvement is a poor prognostic sign, with death occurring in the majority of severe cases, usually within a few months of birth.^{433,434} Common causes of death include high-output congestive cardiac failure associated with arteriovenous shunts (particularly in the liver), central nervous system complications, and bleeding associated with the Kasabach–Merritt syndrome.^{433,435-439} This syndrome has been cured by the surgical excision of a complex vascular lesion in an infant.⁴⁴⁰ It was segmental rather than diffuse. Other developmental abnormalities have been reported in association with this condition.⁴⁴¹

Hemangiomas of the head and neck region are sometimes associated with anomalies of the major blood vessels, including aortic coarctation.⁴⁴² They are not strictly diffuse but, rather, *segmental* in distribution. One such syndrome is PHACES (*posterior fossa malformations, hemangiomas* – especially large, plaque-like, facial lesions – *arterial anomalies, cardiac anomalies, eye abnormalities, and sternal cleft and/or supraumbilical raphe*).^{371,443-447} In PHACES (OMIM 606519), nearly 90% of affected individuals are females. In 70% of cases, there is only one extracutaneous manifestation.^{448,449} *Forme frustes* may occur.⁴⁵⁰ Linear hypopigmentation has also been reported.⁴⁵¹ Other syndromic presentations include lumbosacral hemangiomas of infancy associated with spinal dysraphism⁴⁵² or genitourinary abnormalities and also hepatic hemangiomas with cutaneous and sometimes thyroid abnormalities.⁴⁴⁹ Large perineal hemangiomas are another segmental (rather than diffuse) form with associated defects. PELVIS syndrome refers to the presence of *perineal hemangioma, external genitalia malformations, lipomyelomenigocele, vesicorenal abnormalities, imperforate anus, and skin tag*.⁴⁵³ Becaplermin gel has been used to treat ulcerated perineal hemangiomas in a small series.⁴⁵⁴

A purely cutaneous form of diffuse neonatal hemangiomatosis has also been reported and has been called '**benign neonatal hemangiomatosis**'.⁴⁵⁵⁻⁴⁵⁷ The prognosis in this group is good. In these patients, and in some survivors of those with visceral hemangiomas, spontaneous regression of lesions occurs.^{455,456,458} In one such case with only cutaneous lesions, the lesions had all resolved by 2 years of age.⁴⁵⁹

Histopathology of infantile hemangioma

Early lesions are highly cellular and involve the dermis, but extension into the subcutis may occur. Vascular lumina are small, often slit-like and unapparent, and they are lined by plump endothelial cells (Fig. 38.16). Moderate numbers of normal mitotic figures are present, and mast cells and dermal dendrocytes are frequent in the intervening stroma.⁴⁶⁰ It has been suggested that the mast cells may play a role in angiogenesis and therefore in the formation of these lesions.⁴⁶¹ The vascular proliferation often has a marked lobular configuration; this is

Figure 38.16 (A) Hemangioma of infancy. (B) The lumina are slit-like and unapparent. (H&E)

often more obvious in the subcutis. Here, fat lobules are partly or completely replaced, and the appearance may resemble that of angiolipomas.³⁷⁷ Perineural infiltration can be present.⁴⁶² This was in a cellular infantile variant. This finding is unusual in light of a more recent finding that nerve bundles are absent in hemangiomas but present in vascular malformations.⁴⁶³ Lesions with vessel proliferation, in and around sweat glands, have also been described.⁴⁶⁴ As the lesions evolve, vascular lumina become larger and more obvious. A central draining lumen may become evident in each lobule. The endothelium lining the vessels becomes flatter. With regression of lesions, there is disappearance of vessels, interstitial fibrosis, and fat replacement of vascular tissue in the lobules of the subcutis.³⁷⁷ Immunohistochemical studies have demonstrated endothelial (CD31⁺) and pericytic (SMA⁺) differentiation in cells.⁴⁶⁵ The early involution phase is characterized by ICAM-1 (CD54) expression and a sparse infiltrate of CD8⁺ cells.³⁷⁰ The endothelial cells express GLUT-1, in contrast to malformations. They also express Lewis Y antigen (LeY), merosin, and CD15.^{370,466} The transcription factor encoded by the Wilms' tumor 1 (*WT1*) gene is expressed in the endothelium of hemangiomas but not in vascular malformations.²¹³ It is also expressed in angiosarcomas.⁴⁶⁷

Electron microscopy

Ultrastructural studies of capillary hemangiomas have shown plump endothelial cells surrounded by a basement membrane and pericytes.¹¹¹

Figure 38.17 Sinusoidal hemangioma. There is a lobular pattern, with interconnecting vascular channels. (H&E)

Intracytoplasmic vacuoles are present in endothelial cells, and they are thought to represent an early stage in lumen formation.⁴⁶⁸ Crystalloid inclusions have been identified in endothelial cells in early cellular lesions.⁴⁶⁹ Vessels within a hemangioma may have features of capillaries, venules, or arterioles.¹¹¹

Differential diagnosis

Infantile hemangiomas can clinically mimic other tumors. In a study of 423 children referred with a diagnosis of 'hemangioma', that diagnosis was confirmed in 89% of cases; 7% were found to have vascular malformations, 2% other benign anomalies, and 2% malignant lesions.⁴⁷⁰ Congenital infantile fibrosarcoma is one of the malignancies that can resemble hemangioma.⁴⁷¹ While investigating the mechanism for propranolol's favorable effect on proliferating infantile hemangiomas, Rossler *et al.* found that expression of β_1 -adrenoceptor mRNA is markedly higher in infantile hemangiomas compared to β_2 -adrenoceptor mRNA, whereas in lymphatic malformations the situation is reversed, and venous malformations showed low expression of all β -adrenoceptor mRNAs.⁴⁷²

SINUSOIDAL HEMANGIOMA

Sinusoidal hemangioma is an uncommon benign vascular tumor with some similarities to a venous malformation ('cavernous' hemangioma). However, it occurs as an acquired lesion in adults rather than in children.⁴⁷³ This variant is most common in females, with the trunk (including the breast) and limbs being the most common sites. The tumor involves the subcutis and deep dermis.

It is an acquired lesion and has therefore not been included with the 'hamartomas and malformations'.

Histopathology⁴⁷³

A lobular architecture is characteristic of sinusoidal hemangioma (Fig. 38.17). Lobules are composed of thin-walled interconnecting vascular channels forming a sinusoidal pattern. Vessels are closely approximated, with little intervening stroma. Tangential sectioning of vessel walls produces a pseudopapillary pattern. Unlike typical 'cavernous' hemangiomas, lining cells may appear focally atypical with nuclear hyperchromatism. Mitotic figures are not seen. Calcification is a rare complication,⁴⁷⁴ and it may be seen along with thin bands of hyalinized collagen, recent or organized thrombi, metaplastic ossification, and

foamy macrophages – features associated with ‘ancient’ change.⁴⁷⁵ The one study that investigated the issue found that a sinusoidal hemangioma in a 59-year-old man was WT1 positive and GLUT1 negative, arguing, respectively, against a vascular malformation or an infantile hemangioma.⁴⁷⁶

HEMANGIOBLASTOMA

Hemangioblastomas are intracranial or intraspinal tumors arising sporadically or in association with von Hippel–Lindau syndrome (OMIM 193300). Two cases have been reported in the skin – one on the nose,⁴⁷⁷ and the other in the soft tissue of the inner ankle.⁴⁷⁸ The lesion from the nose did not recur, despite its treatment by shave excision. In addition, a case of cerebellar hemangioblastoma was associated with diffuse neonatal hemangiomatosis.⁴⁷⁹

Histopathology

The lesions were composed of sheets of vacuolated⁴⁷⁸ or clear cells,⁴⁷⁷ with intervening vessels ranging from small capillaries to large ectatic, thin-walled vessels. In the case with vacuolated cells, there was some resemblance to a lipoma.⁴⁷⁸ This case also showed focal necrosis and some stromal hemosiderin. The tumor cells stained for neuron-specific enolase and calponin but not for HMB-45, epithelial membrane antigen, or glial fibrillary acid protein (GFAP). Some cells were S100 positive in one case but not the other. The vascular endothelial cells expressed CD31 and CD34.

‘CHERRY’ ANGIOMA

‘Cherry’ angiomas (senile angiomas, Campbell de Morgan spots) are very common single or multiple bright red papules, up to a few millimeters in diameter, that occur predominantly on the trunk and proximal parts of the limbs. There is typically a pallid halo surrounding the lesions. Rare before puberty, the incidence increases sharply in the fourth decade such that they are almost universal in old age.⁸³ They were common in Iranian veterans, many years after exposure to sulfur mustard poisoning.⁴⁸⁰ A case with early onset lesions has been reported in association with nevus flammeus (capillary malformation).⁴⁸¹

Treatment options are many. It can be removed by surgical, punch, or shave excision. Cryosurgery and electrodesiccation are other options. Laser-treated lesions undergo inflammation, necrosis, and eventual healing by 4 weeks.⁴⁸²

Histopathology

In small early lesions, one or more dilated interconnecting thin-walled vascular channels are present in the dermal papillae. In older lesions, there is loss of rete ridges and atrophy of the superficial epidermis, with formation of a polypoid lesion composed of a network of dilated communicating channels with scant intervening connective tissue (Fig. 38.18). A collarette may be present at the periphery of the lesions.

These lesions appear to be the dilated and interconnected segments of venous capillaries and postcapillary venules in the dermal papillae. The vessels of the upper horizontal plexus are not involved. The non-replicating nature of the endothelial cells comprising these lesions indicates that they are probably not true neoplasms.⁴⁸³ The high incidence of these lesions in old age suggests that their occurrence is an age-related degenerative phenomenon.

A case with the histological appearances of this entity but clinical features of discrete agminated red papules coalescing into a plaque has been reported. It was called ‘acquired agminated acral angioma’.⁴⁸⁴

Figure 38.18 ‘Cherry angioma’. This polypoid lesion is composed of dilated vascular channels and scant intervening stroma. A collarette is present at the periphery. (H&E)

GLOMERULOID HEMANGIOMA

Chan and colleagues coined the term ‘glomeruloid hemangioma’ for a characteristic benign vascular tumor that they considered a cutaneous marker for POEMS syndrome (Crow–Fukase syndrome).^{485–489} POEMS syndrome is a multisystem disorder characterized by polyneuropathy (peripheral sensorimotor neuropathy, papilledema), organomegaly (hepatosplenomegaly, lymphadenopathy), endocrinopathy (impotence, gynecomastia, amenorrhea, glucose intolerance, hypothyroidism, adrenal insufficiency), M-protein (paraproteinemia, osteosclerotic myeloma, marrow plasmacytosis), and skin changes (hyperpigmentation, hypertrichosis, sclerodermoid features, and hemangiomas).^{490,491} Diffuse skin hyperpigmentation is the most common skin finding, seen in more than 90% of patients.⁴⁹² Multicentric Castleman’s disease and POEMS syndrome are overlapping conditions.^{493,494} Human herpesvirus type 8 (HHV-8) has not been present in several cases of this combined disease.^{495,496}

Vascular tumors in POEMS syndrome are eruptive, multiple, red or purple in color, and distributed on the trunk and limbs. Lesions are usually small papules from pinhead in size to a few millimeters, although larger, bluish subcutaneous compressible tumors have also been described.⁴⁹⁷ One larger lesion with cerebriform features has been reported.⁴⁸⁷ The tumors have variously been described as showing features of cherry angioma, capillary hemangioma, cavernous hemangioma, lobular hemangioma (pyogenic granuloma and tufted angioma), and targetoid hemangioma.⁴⁹⁸ Lesions may show overlapping features.^{339,497,499,500} Glomeruloid hemangiomas appear to be more common in the Japanese than in other races or ethnic groups.

There have now been several reports of glomeruloid hemangiomas occurring in the absence of POEMS syndrome. In each case, they presented as solitary lesions.^{501–504}

Histopathology⁴⁸⁵

In the characteristic glomeruloid hemangiomas described by Chan *et al.*, there are dilated (sinusoidal) dermal vascular spaces filled by grape-like aggregates of small capillary vessels, resulting in structures resembling renal glomeruli (Fig. 38.19). Between these small vessels are plump cells that appear to be endothelial cells, being positive for factor VIII-related antigen. These cells and endothelial cells lining vessels contain PAS-positive eosinophilic globules, which stain for immunoglobulins at their periphery. In the cases reported without accompanying POEMS syndrome, these eosinophilic globules expressed both κ

Figure 38.19 Glomeruloid hemangioma. Sinusoidal dermal vascular spaces contain grape-like aggregates of small capillary vessels. This biopsy was obtained from a patient with POEMS syndrome. (H&E)

and λ in a polytypical manner.⁵⁰² Electron microscopy has suggested that the globules are enlarged secondary lysosomes (thanatosomes).⁵⁰⁵

A study has shown endothelial cells with two different immunophenotypes.⁴⁸⁶ The capillary-type endothelium had a CD31⁺/CD34⁺/UEA 1⁺/CD68⁻ phenotype, whereas the sinusoidal endothelium had a CD31⁺/CD34⁺/UEA 1⁻/CD68⁺ phenotype.⁴⁸⁶ There is increased expression of VEGF.⁵⁰⁶ In cases reported recently without concurrent POEMS syndrome, the endothelial cells and plump, vacuolated cells were positive for CD31 and CD34.⁵⁰⁵ Isolated cells containing PAS-positive globules were positive for CD68.⁵⁰¹

A morphologically distinct vascular tumor has been reported in association with a solitary bone plasmacytoma. It is mentioned here because of the association of some cases of plasmacytoma with POEMS syndrome or Castleman's disease.⁵⁰⁷ The lesion was characterized by an extensive plaque with vascular hyperplasia and dermal mucin deposition.⁵⁰⁷ The acronym AESOP syndrome, reflecting the component parts, has been used.

PAPILLARY HEMANGIOMA

Papillary hemangioma was reported by Suurmeijer and Fletcher in 2007. Their 11 cases presented as a solitary bluish papule in the head and neck region.⁵⁰⁸ Most lesions had been present for several years. None of the patients had systemic disease, including POEMS syndrome (discussed previously). Only one lesion recurred locally, although surgical margins were involved in several cases.

It has been suggested that papillary hemangioma and glomeruloid hemangioma represent the same pathophysiological process.⁵⁰⁵

Histopathology

The lesions were primarily situated in the dermis, but extension into the subcutis occurred in six cases. Discontinuous areas of papillary branching were often present. There were multiple ectatic vessels with predominantly intravascular papillary growth. The papillae had cellular cores containing pericytes and stromal cells, arranged around normal small capillaries.⁵⁰⁸ The surfaces of the papillae were covered by focally swollen endothelial cells containing numerous hyaline globules consistent with dysfunction of the autophagocytic-lysosomal pathway.⁵⁰⁸

Figure 38.20 (A) Arteriovenous hemangioma. (B) It is composed of thick-walled vascular channels. (H&E)

ARTERIOVENOUS HEMANGIOMA

Arteriovenous hemangioma (acral arteriovenous tumor) presents as a solitary, red or purple papule with a predilection for the lips, the perioral skin, the nose, and the eyelids of middle-aged to elderly men.⁵⁰⁹⁻⁵¹¹ Less than 10% are multiple.^{512,513} It is usually asymptomatic. Lesions measure 0.5–1.0 cm in diameter. It has an association with chronic liver disease,^{514,515} epidermal nevus syndrome, and other vascular malformations. Some lesions are probably examples of vascular malformations.⁸¹

Surgical excision is the treatment of choice for superficial lesions. Deep lesions that are also large may require embolization.⁵¹² An acquired digital lesion (see later) has been treated successfully with Nd:YAG laser.⁵¹³

Histopathology^{509,510}

There is a well-circumscribed non-encapsulated collection of large, thick-walled vessels in the upper and mid dermis (Fig. 38.20). These vessels are lined by endothelium and have a fibromuscular wall that contains elastic fibers but no definite elastic laminae. Most vessels have the characteristics of veins.⁵¹⁶ In approximately one-third of cases,

there are thin-walled dilated angiomatous capillaries superficial to the large tumor vessels. The stroma is often myxoid. Estrogen receptors have not been detected in the vessels.⁵¹⁵

Acquired digital arteriovenous malformations are a distinct entity thought to result from shunts between an artery and a vein in a fingertip.^{517–519} Their extent can be determined by ultrasound imaging.⁵¹³ They are composed of thick- and thin-walled vessels, with some of the former having small amounts of smooth muscle in their walls.⁵²⁰ The thin-walled channels are venules. The lesions lack the tumor-like qualities of the arteriovenous hemangioma. Shunts are visible between the two classes of vessels.⁵¹⁷

The **symplastic hemangioma** is akin to other symplastic tumors that are characterized by bizarre, hyperchromatic cells, which represent a degenerative phenomenon.^{387,521} It is composed of thick-walled and variably dilated vessels. The atypical cells, with markedly hyperchromatic nuclei, are located within the vascular smooth muscle wall or in the interstitium (Fig. 38.21). They are spindle or epithelioid in shape; their nuclei may be multinucleate.⁵²¹ Perivascular hemorrhage, vascular thrombosis, and focal papillary endothelial hyperplasia are

Figure 38.21 (A) Symplastic hemangioma. (B) Bizarre cells are in the wall of vessels and in the interstitium. (H&E)

often present. Rare atypical mitoses may be present.⁵²¹ The pleomorphic cells show focal smooth muscle positivity.⁵²¹

MICROVENULAR HEMANGIOMA

Microvenular hemangioma, a benign vascular tumor, occurs predominantly in young and middle-aged adults as a single, slow-growing lesion on the trunk or limbs. Lesions are purple to red papules or nodules, usually less than 1 cm in diameter.^{522–524} Larger plaque forms have been reported,⁵²⁵ and multiple lesions have been described.^{526,527} An association with systemic immunosuppression has been suggested, but there is little evidence to support this view.⁵²⁸

Histopathology⁵²²

The main characteristic of this tumor is a proliferation of thin uniform branching collapsed-looking vessels with inconspicuous lumina. The vessels involve the dermis and occasionally the superficial subcutis. The intervening stroma is collagenous, sometimes with a desmoplastic appearance (Fig. 38.22). Endothelial cells are sometimes plumper than normal but not atypical; they stain for factor VIII-related antigen, CD34, CD31, and *Ulex europaeus*-1 lectin. A peripheral layer of pericytes stains for smooth muscle actin.^{525,529} Microvenular hemangiomas are positive for WT1, negative for GLUT1, and negative for D2-40.⁵³⁰ Eosinophilic globules, commonly seen in Kaposi's sarcoma, are not seen in this tumor.

TARGETOID HEMOSIDEROTIC (HOBNAIL) 'HEMANGIOMA'

Targetoid hemosiderotic (hobnail) 'hemangiomas' are single lesions occurring in young or middle-aged persons, with a male predominance. They involve the trunk or limbs.^{368,531–536} The face is rarely involved.⁵³⁷ Characteristically, the lesion has a 'targetoid' appearance with a violaceous central papule surrounded by an area of pallor and an ecchymotic or brown ring,⁵³⁸ which expands and subsequently disappears. The central papule persists. It has been reported in pregnancy^{532,533} and also in a father and son.⁵³⁹ Rare cases have been reported that altered during the menstrual cycle, becoming larger and painful prior to menstruation.⁵⁴⁰ Lesions may be monitored by dermoscopy.⁵⁴¹

Figure 38.22 Microvenular hemangioma. This image shows branched, collapsed-appearing vessels with (for the most part) inconspicuous lumina and a somewhat desmoplastic stroma. (H&E)

A lymphatic origin has been confirmed by the lymphatic endothelial cell marker D2-40.⁵⁴² Previously, it was thought to have been a traumatized angiokeratoma,⁵³⁶ although a lymphatic origin had been suggested by others.⁵³⁵ HHV-8 has not been demonstrated in this lesion.⁵⁴³ Based on their investigations showing that these lesions are both D2-40⁺ and WT1⁻, Trindade *et al.* believe that hobnail hemangioma should be regarded as a lymphatic malformation rather than a lymphatic neoplasm.⁵⁴⁴

The term ‘**hobnail hemangioma**’ has been used for a group of vascular lesions related to targetoid hemosiderotic hemangioma but encompassing tumors with morphological features of retiform hemangioendothelioma, progressive lymphangioma, and Dabska’s tumor.^{545,546} The term is being used currently as a synonymous nomenclature.⁵⁴⁷ It is the preferred term by some authors, despite its dubious origin. Both terms are now misnomers.

Histopathology⁵³⁸

Initially, there are ectatic vascular channels lined by plump (hobnail) endothelial cells in the upper dermis. The vessels have intraluminal papillary projections. In the deep dermis and subcutis, the channels dissect collagen bundles and surround sweat glands.⁵⁴⁶ There is a variable mild inflammatory infiltrate about vessels and considerable extravasation of erythrocytes and hemosiderin (Fig. 38.23). Fibrin

Figure 38.23 Targetoid hemosiderotic hemangioma. (A) There is no superficial vascular dilatation in this case. (B) There are small vessels and abundant hemosiderin. The lesion was clinically typical. (H&E)

thrombi may be seen in the superficial vessels – a feature not present in the early lesions of Kaposi’s sarcoma. Plasma cells are also uncommon; eosinophilic globules have not been reported. Old lesions are composed of collapsed thin-walled anastomosing vascular channels with hemosiderin. Staining with D2-40, the new lymphatic endothelial marker, shows microshunts between neoplastic lymphatic channels and small blood vessels, explaining the aneurysmal microstructures and the erythrocytes and hemosiderin.⁵⁴⁷

In one series, the tumor cells stained for CD31 in all cases tested, whereas only 3 of the 28 cases stained completely for CD34. In addition, 4 out of 8 cases stained positively for VEGFR-3, suggesting lymphatic differentiation.⁵³⁵ This has been confirmed by the presence of lymphatic marker D2-40, the absence of CD34 staining of endothelial cells, and the lack of actin-labeled pericytes.⁵⁴⁷

Dermoscopy of hobnail hemangioma shows round to oval red blebs (ectatic, thin-walled vessels) and small, round, pale pink structures amid diffuse pink-white pigment (slit-like vascular spaces).⁵⁴⁸

SPINDLE CELL HEMANGIOENDOTHELIOMA (HEMANGIOMA)

Although spindle cell hemangioendothelioma was originally believed to be a vascular tumor of low-grade malignancy,⁵⁴⁹ there is convincing evidence that this entity may in fact represent a non-neoplastic process.^{550–558} Accordingly, Requena and Ackerman believe it should be renamed ‘spindle cell hemangioma’.⁵⁵⁷ Fletcher *et al.* suggested that these lesions represent a reactive vascular process arising in association with a local abnormality of blood flow because the lesions are often associated with local malformation of blood vessels, have an integral smooth muscle component, occasionally regress spontaneously, and do not metastasize.⁵⁵⁰ A similar view has been expressed by Perkins and Weiss.⁵⁵⁴ This tumor has been reported in Maffucci’s syndrome and in association with venous malformations and the Klippel–Trenaunay syndrome.^{549,551,554,559,560}

Although tumors may occur at any age from birth to adulthood, approximately 50% of cases arise before the age of 25 years. Lesions may be single or multiple; multiple lesions tend to occur in a single area. Occasionally, lesions are widespread. The hands and feet are the most common sites, but lesions also occur on the trunk.^{549,561} Oral lesions are rare.⁵⁶² Tumors are circumscribed, hemorrhagic nodules. They may increase in size and number with time, often over a long period. Local recurrence of lesions is common after removal. In one study, ‘recurrences’ were noted to arise in adjacent, previously unaffected tissue, suggesting a new lesion. Such recurrences may arise from contiguous spread along or multifocal involvement of a vessel.⁵⁵⁴ There is only one documented case of metastasis by this tumor, and that followed multiple recurrences, radiotherapy, and transformation to a conventional angiosarcoma.⁵⁴⁹

Histopathology^{549,550}

Tumors are situated in the dermis and subcutis; rarely, they occur in the lumen of a vein. There are three main components. The first is a vascular component of thin-walled cavernous channels that may contain thrombi or phleboliths. The second is a solid area of spindle cells with slit-like vascular spaces; these areas may resemble Kaposi’s sarcoma (Fig. 38.24). The third component is plump endothelial cells, either in groups or lining vascular channels. Some of these cells have intracytoplasmic vacuoles. Fletcher *et al.* also noted the frequent presence of large, malformed, thick- or thin-walled vessels adjacent to the tumor, as well as bundles of smooth muscle cells near cavernous vessels or in solid areas.⁵⁵⁰ Nuclear atypia is minimal; mitoses are rarely seen. Lymphocytes and siderophages may be associated with the lesions, but

Figure 38.24 (A) Spindle cell hemangioendothelioma. (B) There are thin bundles of spindle cells between the vascular channels. (H&E)

eosinophilic globules, as seen in Kaposi's sarcoma, have not been reported. The spindle cells in this tumor are generally more bland-looking and regular in appearance than those in Kaposi's sarcoma. Furthermore, the spindle cell fascicles are not as well-formed as those in Kaposi's sarcoma.⁵⁶³

Immunohistochemical studies have confirmed the endothelial nature of the cells lining cavernous channels that stain for CD31, CD34, factor VIII-related antigen, and *Ulex europaeus*-1 lectin. Solid epithelioid and spindle cell areas are negative for these antigens.⁵⁵⁰ Interleukin-8 (IL-8) is also expressed.⁵⁶⁴ Lesions do not contain HHV-8. DNA flow cytometric and immunohistochemical studies have shown that this tumor has low proliferative activity and is diploid, consistent with a reactive lesion.⁵⁵¹

Diagnosis has been made on fine needle aspiration cytology, with which there were single and clustered spindle and epithelioid cells with oval, vesicular nuclei, occasional intranuclear pseudoinclusions, and moderate, eosinophilic cytoplasm; vascular spaces were also observed in the cell block preparation.⁵⁶⁵

Electron microscopy

Ultrastructural studies have shown a heterogeneous cell population in solid areas; however, occasional cells contain Weibel-Palade bodies, confirming that some cells are showing endothelial differentiation.

Figure 38.25 Elastotic hemangioma. There is a proliferation of small blood vessels that are arranged parallel to the surface. (H&E)

ACQUIRED ELASTOTIC HEMANGIOMA

Acquired elastotic hemangioma arises on the sun-damaged skin of middle-aged to elderly persons. Although all six cases in the original report by Requena and colleagues were women, two of the five cases seen by the author have been in males.⁵⁶⁶ Clinically, lesions present as solitary plaques on the dorsal aspect of the forearms and, less commonly, the lateral neck.⁵⁶⁶ They are rarely diagnosed as vascular lesions clinically.

Histopathology

There is a broad, band-like proliferation of capillary blood vessels in the superficial dermis, arranged parallel to the surface and associated with marked solar elastosis (Fig. 38.25).^{566,567} In a recent report of 10 cases, all vessels stained for CD34, but only 1 of the 10 expressed the lymphatic endothelial marker podoplanin (D2-40).⁵⁶⁷

ANGIOMA SERPIGINOSUM

Angioma serpiginosum is a rare condition in which multiple pin-sized vascular puncta occur either singly or in clusters on any part of the body except mucous membranes and the palms and soles.^{568,569} The legs are the most common site. Extensive cutaneous involvement and linear lesions along the lines of Blaschko have been reported.⁵⁷⁰ Lesions appear before puberty and progress by the development of further puncta at the periphery of the involved area. Late onset has been recorded.⁵⁷¹ The lesions do not regress. Females are more commonly affected, and a familial grouping of cases has been reported;^{572,573} however, the mode of transmission is still unclear, with the likelihood of X-linked (OMIM 300652) and autosomal dominant forms (OMIM 106050).

Figure 38.26 Angioma serpiginosum. There are grouped, ectatic, congested capillaries with surrounding downgrowth of rete ridges – an image resembling angiokeratoma. (H&E)

Histopathology

Microscopic examination shows single or grouped ectatic, congested, thin-walled capillaries in the papillary dermis. Thick-walled capillaries and downgrowth of the rete ridges between groups of vessels have also been described.^{574,575} The latter lesions resemble angiokeratomas (Fig. 38.26). Inflammation is not usually present. Although previously regarded as a telangiectatic process, an element of vascular proliferation appears to be present.⁵⁷⁴

Dermoscopy has shown sheet-like arrangements of ‘discrete red lagoons’.⁵⁷⁶ On reflectance confocal microscopy, there were dilated vessels in the superficial dermis oriented perpendicular to the epidermis and a deeper vascular plexus oriented parallel to the epidermal surface. Poorly refractile small cells (erythrocytes) were found moving rapidly in the central portions of vessel lumina, with brightly refractile cells (neutrophils) at the luminal periphery.⁵⁷⁶

GIANT CELL ANGIOBLASTOMA

Only a few cases of giant cell angioblastoma, an exceedingly rare tumor of skin and soft tissues, have been reported.⁵⁷⁷ The tumor is present at birth or noted soon after. It is locally infiltrative but grows slowly. The morphology suggests an unusual form of neoplastic angiogenesis.⁵⁷⁷ Metastases have not been recorded.

Histopathology⁵⁷⁷

There are concentric arrays of oval to spindle cells around small endothelium-lined channels. These primitive cells arranged around the vessels tend to differentiate toward pericytes and express smooth muscle actin while the endothelial cells express CD31 and factor VIII-related antigen. Large mononuclear and multinucleate giant cells are also present. Perineural and intraneural involvement by small vessels is common. A stromal infiltrate of lymphocytes and plasma cells is another feature.

EPITHELIOID ANGIOMATOUS NODULE

Epithelioid angiomatous nodule is a very rare vascular tumor described by Brenn and Fletcher in 2004.⁵⁷⁸ The lesions are mostly solitary and involve the trunk, the head and neck,⁵⁷⁹ and, less often, the

extremities.⁵⁸⁰ Rare cases present as eruptive,⁵⁸¹ recurring nodules. An example arising in a capillary malformation has been described.⁵⁸² Despite vague resemblance to epithelioid hemangioendothelioma, the lesion is quite benign.⁵⁸³ There is an absence of microsatellite instability.

Surgical excision is curative. The eruptive cases (discussed previously) cleared with corticosteroids, only to recur later.⁵⁸⁰

Histopathology^{578,580}

The lesion is often situated in the upper dermis. Sometimes it involves the deep dermis. It is a circumscribed, mainly solid proliferation of large polygonal epithelioid cells with eosinophilic cytoplasm, with enlarged nuclei and prominent nucleoli.^{578,580} Vascular channels with epithelioid endothelium are either focal or diffuse. There are extravasated erythrocytes and hemosiderin pigment in more than half. There is a scant inflammatory infiltrate, predominantly of lymphocytes. Eosinophils have been prominent in a few cases. Mild fibrosis may be present.

The cells express CD31 and CD34, but the latter is often focal. Smooth muscle actin labels pericytes.⁵⁸³ In one case, peripheral vessels expressed D2-40.⁵⁸⁴ Cells are negative for HHV-8, S100, epithelial membrane antigen (EMA), and the cytokeratin marker AE1/AE3.⁵⁸³ In a recent case – a lesion of long duration on the chest wall of a woman with a history of breast cancer – the lesional cells were also positive for EMA and estrogen receptor with a low proliferation index as assessed with Ki-67.⁵⁸⁵

ANGIOLYMPHOID HYPERPLASIA WITH EOSINOPHILIA (EPITHELIOID HEMANGIOMA)

Angiolymphoid hyperplasia with eosinophilia (ALHE) is a tumor of skin and subcutaneous tissues composed of vessels, a proliferation of a distinctive type of endothelial cell, and a variable component of inflammatory cells.⁵⁸⁶ Whether it is a true neoplasm or a reactive process is currently undecided. It appears to be identical to the lesions known as epithelioid hemangioma, pseudopyogenic granuloma, atypical pyogenic granuloma, histiocytoid hemangioma, intravenous atypical vascular proliferation, and nodular angioblastic hyperplasia with eosinophilia and lymphofolliculosis.^{587–592}

Kimura’s disease (eosinophilic lymphogranuloma),^{593–597} although previously included by some in this group of conditions, is a separate entity.^{598–600} It is clinically different, typically presenting as large subcutaneous masses in young to middle-aged Asian men. It has been reported in non-Asians.⁶⁰¹ Coexistence of the two conditions in the same patient suggests they may be part of a spectrum.^{602,603} The majority of lesions are located around the ears or in the parotid gland.⁶⁰⁴ A case presenting with widespread prurigo nodularis-like lesions has been reported.⁶⁰⁵ Elevated serum immunoglobulin E levels and peripheral blood eosinophilia are also common.⁶⁰⁶ The etiology of Kimura’s disease is unknown, but it may be an aberrant immune reaction to an as yet unknown stimulus. Epstein–Barr virus DNA has been detected in lesional tissue in one case.⁶⁰⁷ Clonal populations of T cells have been detected in some patients.⁶⁰⁸ Treatment includes surgical resection and regional or systemic corticosteroid therapy. Cytotoxic therapy, cyclosporine (ciclosporin),^{609,610} and radiation have also been used.⁶⁰⁶ The disease has a good prognosis, but it may recur locally. Death from Kimura’s disease is rare.⁶⁰¹

In *angiolymphoid hyperplasia*, lesions involve the subcutaneous tissue or the dermis or both. Single or multiple pink to red-brown papules or nodules occur, predominantly on the face, scalp, and ears; they are uncommon on the limbs and trunk. There is a predilection for the retroauricular area.⁶¹¹ Widespread lesions and multiple lesions limited to one limb have been reported.^{612–614} Cases have been reported

in a port wine stain,⁶¹⁵ over a deep vascular malformation,⁶¹⁶ and on the vulva,^{590,617} penis,^{618,619} lip,⁶²⁰ inner canthus,⁶²¹ and oral mucosa.^{622,623} It has been reported in association with pregnancy,^{624,625} HIV infection,⁶²⁶ lichen amyloidosis,⁶²⁷ and the nephrotic syndrome.⁶²⁸ It may mimic Bowenoid papulosis.⁶¹¹ Symptomatic lesions may be painful, pruritic, or pulsatile.⁶²⁹ In some series, there is a female predominance.⁶³⁰ Young to middle-aged people are most commonly affected. Some cases are associated with a blood eosinophilia. Lesions may remain for years without evidence of involution, and they may recur after excision.⁵⁹¹ Peripheral T cell lymphoma and severe atherosclerosis developed in an adolescent with multiple lesions of ALHE.⁶³¹ The authors of the paper believed that the pathology of these conditions was related.⁶³¹

The true nature of this lesion is uncertain. A few examples appear to be associated with trauma,⁶³² oral contraceptives,^{629,633} HIV infection,⁶²⁶ or pregnancy but not HHV-8 infection.^{613,634,635} It has been suggested that the lesions are a reactive hyperplastic process secondary to an underlying arteriovenous malformation or traumatic pseudoaneurysm.^{368,636,637} The IL-5 levels are increased, which may explain the eosinophilia.^{637,638} Clonal populations of T cells have been detected in some but not all of the cases tested.^{634,639,640}

Many different treatments have been used for this condition, suggesting that no treatment method is universally successful. Many are surgically excised. They can also be treated by laser therapy,⁶⁴¹ most often the pulsed dye laser.^{614,642–644} Cryosurgery⁶⁴⁵ and electrosurgery are other options. Intralesional corticosteroids, IFN- α ,^{646,647} and bleomycin⁶⁴⁸ have also been used. Tacrolimus ointment⁶⁴⁹ and the anti-IL-5 antibody mepolizumab⁶⁵⁰ have both produced cures.

Histopathology

The lesions consist of circumscribed collections of vessels and inflammatory cells. The vascular component comprises thick- and thin-walled vessels lined by plump endothelial cells (Fig. 38.27). These cells also occur in clumps that appear solid or sometimes contain small lumina. They are 'epithelioid' in appearance, with a large nucleus and abundant eosinophilic cytoplasm, and are characteristic of this condition. Prominent cytoplasmic vacuoles are seen in some cells. Normal mitotic figures are sometimes present. Intravascular proliferations of these cells may be seen in the lumina of larger vessels.⁵⁹⁰ Exuberant examples may be confused with epithelioid hemangioendothelioma and epithelioid angiosarcoma.⁶¹⁸ There is one report of multinucleated cells, some of which were endothelial sprouts and others fibrohistiocytic cells.⁶⁵¹ Associated with the vascular and endothelial proliferations is a stromal cellular infiltrate that varies in intensity and consists of lymphocytes (sometimes with lymphoid follicle formation), eosinophils, and mast cells. The stroma may be fibrous or myxoid in character. Sometimes the fibrotic reaction is excessive. In one case, it was associated with a florid granulomatous reaction with many multinucleated giant cells, often of Touton type.⁶⁵²

A rare intra-arterial variant has been described. There was a prominent lymphocytic rim-like component.⁶⁵³

Although these epithelioid cells share some enzymes with histiocytes,⁶⁵⁴ they do not contain lysozyme; they have ultrastructural features of endothelial cells, including Weibel–Palade bodies.⁶²⁹ The epithelioid cells stain for CD31, CD34, factor VIII-related antigen, and *Ulex europaeus*-1 lectin but not for cytokeratins or epithelial membrane antigen.^{655,656} The vacuoles in their cytoplasm possibly represent primitive vascular lumina.

Kimura's disease is composed of reactive lymphoid follicles with a dense infiltration of eosinophils, sometimes forming eosinophilic abscesses.^{601,657–659} An eosinophilic epithelioid granulomatous reaction with central eosinophilic abscesses has been reported.⁶⁶⁰ Mast cells are increased.^{659,661} Vessels (postcapillary venules) are increased in number, but their endothelial cells are usually flat.⁶⁰¹ Vascular cords are unusual.⁶¹²

Figure 38.27 (A) Angiolymphoid hyperplasia with eosinophils. (B) The vascular channels are lined by plump, partly vacuolated endothelial cells. There are scattered eosinophils in the stroma. (H&E)

'**Angiolymphoid hyperplasia with high endothelial venules**' is the term suggested for a cutaneous lesion with a characteristic admixture of lymphoid hyperplasia (without eosinophils) and a vascular proliferation previously called APACHE (see p. 1213).⁶⁶² APACHE continues to be the designation attached to this entity. It appears to be a 'pseudolymphoma'.^{663–665}

Differential diagnosis

An admixture of reactive eosinophils and lymphocytes is common in lesions termed ALHE but may be absent or underdeveloped in other lesions designated 'epithelioid hemangioma'. Thus, in a global sense, lymphoid and eosinophilic infiltrates in epithelioid hemangiomas are not as predictably prominent as they are in Kimura's disease, and the formation of lymphoid follicles is quite uncommon. In contrast to Kimura's disease, only very rare cases of epithelioid hemangioma are associated with peripheral eosinophilia and hyperglobulinemia of the IgE type, even though both lesions favor the skin of the head and neck. Moreover, the rate of recurrence of these proliferations differs after surgical excision; approximately 10% of epithelioid hemangiomas recur after surgery, contrasted with 75% in cases of Kimura's disease. In addition, 50–60% of patients with Kimura's disease have regional lymphadenopathy, whereas the lymph nodes are normal in individuals with epithelioid hemangioma. A resemblance between both ALHE and

Kimura's disease and the recently described IgG4-related disease (see Chapter 40) has been described on several occasions. The latter can have nodular infiltrates around venules composed of lymphocytes, eosinophils, and plasma cells, while at the same time, Kimura's disease has been reported to contain IgG4⁺ plasma cells.⁶⁶⁶ However, a recent report of a case of IgG4-related disease involving the skin that resembled ALHE did not describe epithelioid or histiocytoid endothelial cells.⁶⁶⁷ Furthermore, Kimura's disease involving lymph nodes features IgE in follicular dendritic cells and eosinophilic microabscesses – findings not described to date in IgG4-related disease.⁶⁶⁶ No doubt, much more will be learned about the relationship of ALHE, Kimura's disease, and other conditions to IgG4-related disease in the near future.

LOBULAR CAPILLARY HEMANGIOMAS

The term 'lobular capillary hemangiomas' refers to a group of vascular tumors characterized by the presence of capillary-sized vessels arranged in lobules.^{668,669} Included in this category are pyogenic granuloma and its variants, acquired tufted angioma (angioblastoma, progressive capillary hemangioma),⁶⁶⁸ and glomeruloid hemangioma. The infection-related angiomatoses (bacillary epithelioid angiomatosis and verruga peruana) may also have a lobular pattern.

Pyogenic granuloma and variants

Pyogenic granuloma is a common benign vascular tumor of mucous membranes and skin. Studies suggest that it represents a hemangioma and not simply a florid proliferation of granulation tissue.⁶⁷⁰⁻⁶⁷² Common sites include the gingiva, lips, fingers, and face.^{673,674} Periungual lesions may develop, sometimes along Beau's lines.^{675,676} Less common sites include the trunk, vulva,⁶⁷⁷ arms, legs, and conjunctiva.⁶⁷⁸ There is a 3:2 male preponderance.⁶⁷⁴ These tumors are commonly polypoid and pedunculated, but they may be sessile. Most are red or red-brown in color. Some darker lesions may clinically mimic nodular malignant melanoma. The lesions typically evolve rapidly to maximum size over a period of weeks. In one series, this varied from 0.5 to 4 cm, with a mean diameter of 1.1 cm.⁶⁷⁹ The surface is often ulcerated and bleeds easily.

Spontaneous involution of lesions is uncommon but has been reported in cases of disseminated pyogenic granuloma⁶⁸⁰ and also postpartum in women who develop lesions during pregnancy (epulis gravidarum).⁶⁸¹ The lesions may develop at any age, and both sexes are affected. There is a female predominance in some reports⁶⁸² but not in others.⁶⁸³ In one series of oral and nasal mucosal lesions, there was a marked male predominance in the first two decades and a female predominance during the childbearing years.⁶⁷⁰ Children most commonly develop this tumor after the age of 1 year; rarely, congenital lesions occur.⁶⁷⁸ Occasionally, the tumors may be multiple or disseminated.^{680,684-688} Multiple satellite recurrences sometimes occur after treatment of the primary lesion, particularly when the latter was on the trunk, an uncommon site for pyogenic granuloma.⁶⁸⁹⁻⁶⁹¹ A giant recurrent pyogenic granuloma has been reported on the face. It had satellitosis.⁶⁹² Satellite vascular lesions resembling a vascular malformation have been reported following removal of a nevocellular nevus.⁶⁹³ Pyogenic granulomas have been reported in a pre-existing nevus flammeus,⁶⁹⁴ a port wine stain,^{678,695,696} unilateral dermatomal superficial telangiectasia,⁶⁹⁷ and a 'spider' angioma.⁶⁹⁸ Recurrent intrapapillary endothelial hyperplasia has developed at the site of a previously excised pyogenic granuloma.⁶⁹⁹ Pyogenic granulomas developed in the mouth of a patient with oral pemphigus vulgaris.⁷⁰⁰

In the majority of cases, there is no apparent cause for these lesions; a minority follow trauma,^{670,678,679,701} retinoid therapy (both topical and systemic),⁷⁰²⁻⁷⁰⁷ granulocyte colony-stimulating factor therapy,⁷⁰⁸ reverse transcriptase inhibitor therapy,⁶⁷⁶ insect bite,⁶⁷⁸ burn,^{655,688} scald,⁷⁰⁹ or

cryotherapy.⁷¹⁰ Pyogenic granulomas of the nail bed region have been reported following the use of capecitabine,^{711,712} gefitinib,⁷¹³ and systemic 5-fluorouracil.⁷¹⁴ The higher incidence in women during the childbearing years, the occurrence in pregnancy, an association with use of the oral contraceptive pill, and the spontaneous regression of lesions following parturition suggest that a hormonal factor is involved in their genesis.⁶⁸¹ This theory has been disputed for cutaneous pyogenic granulomas but not for mucosal ones.^{683,715,716} Unlike bacillary angiomatosis, there is no association with *Bartonella* infection.⁷¹⁷ It has also been suggested that pyogenic granulomas represent small acquired arteriovenous fistulae.⁶⁷³ Immunohistochemical and ultrastructural studies have confirmed that pyogenic granulomas are tumors of vessels and endothelial cells.^{718,719} Recent work indicates that, like angiosarcomas, they express various activators of specific transcription factors.⁷²⁰

Pyogenic granuloma can be treated by a single shave and electrocautery,⁷²¹ curettage with electrodesiccation, or surgical excision. A randomized trial found that curettage followed by electrodesiccation gave better cosmetic results and required fewer treatments than did cryotherapy.⁷²² Laser therapy has also been used. Topical imiquimod 5% cream has been used for recurrent lesions⁷²¹ and for focal facial lesions.⁷²³ It may be used under occlusion.⁷²⁴ A novel treatment for polypoid lesions is the use of a suture around the base.⁷²⁵

Histopathology

Pyogenic granulomas are lobular capillary hemangiomas (Fig. 38.28).⁶⁷⁰ The lobular arrangement of the lesions is distinct from the pattern of capillaries in granulation tissue, and unlike granulation tissue, the capillaries do not usually involute with time. The underlying morphology is often obscured by secondary ulceration, edema, hemorrhage, and inflammatory changes. In uncomplicated lesions, there is a lobulated proliferation of capillary-sized vessels. The deep lobules are compact and cellular, with small indistinct lumina. Occasional mitotic figures may be seen within the cellular lobules. The apoptotic rate is low, possibly a reflection of its rapid growth.⁷²⁶ Toward the surface, the lobules are larger and less tightly packed, and they have distinct capillaries with larger branching lumina. The lobules are separated by myxoid or fibrous connective tissue septa.⁷²⁷ The rare presence of spindle cells may mimic Kaposi's sarcoma.⁷²⁸ A lobulated variant of Kaposi's sarcoma mimicking pyogenic granuloma has been reported.⁷²⁹ Extramedullary hematopoiesis has been reported in the stroma in two cases.^{730,731}

The surface epithelium is attenuated, and at the margins of the lesion there is often an epidermal collarette formed by elongated rete ridges or sweat ducts. Surface ulceration and inflammation are

Figure 38.28 Pyogenic granuloma. There is a well-developed collarette at the margins of this lobular vascular proliferation. (H&E)

secondary events, and they sometimes lead to the formation of true granulation tissue near the surface of the lesions. Mast cells are not increased in pyogenic granuloma, unlike proliferative-phase hemangiomas.^{461,678}

Lesions with the same lobular hemangiomatous pattern have also been described within veins⁷³² and in subcutaneous tissues.^{733,734} *Intravenous pyogenic granuloma* occurs predominantly on the neck, arms, and hands.^{732,735–737} The lesions are composed of a lobular proliferation of capillaries set in a fibromyxoid stroma. A fibrovascular stalk usually connects the lesion to the intima of the involved vein.⁷³⁸ *Subcutaneous pyogenic granuloma* occurs predominantly on the upper extremities.⁷³³

Immunohistochemistry is rarely carried out because the diagnosis can easily be made on light microscopy. It may be performed in atypical and multiple lesions. The vascular markers CD31, CD34, and factor VIII are positive. Lesions are negative for the glucose transporter GLUT-1.⁷⁰⁸

Dermoscopy is a useful tool for improving the recognition of these lesions. There is a reddish homogeneous area surrounded by a white collarette.⁷³⁹

Acquired tufted angioma (angioblastoma)

Wilson Jones first gave the name acquired tufted angioma to an unusual acquired vascular proliferation^{740,741} that had previously been reported as progressive capillary hemangioma⁷⁴² and ‘angioblastoma (Nakagawa)’ in the Japanese literature.^{743,744} The Japanese cases have some clinical differences and may not be identical to acquired tufted angioma, although the current consensus is that they are the same entity.⁷⁴⁵ More than 200 cases have now been reported. The condition is characterized by slowly spreading erythematous macules, plaques, and nodules; rarely, there are multiple lesions.³⁷¹ Raised papules resembling pyogenic granulomas are sometimes seen within the lesion.^{668,746} This vascular tumor occurs predominantly in children and young adults, but it has also been reported in older individuals.^{747–749} Congenital cases are rare.^{745,750} Lesions arise most commonly on the neck and upper trunk but also at other sites,^{751–753} including the eyelids;⁷⁵⁴ they are sometimes painful.^{751,755,756} Lesions can become quite large.^{757–759} Hypertrichosis has been present in several cases.^{756,759} Platelet trapping in the lesions, producing the Kasabach–Merritt syndrome, is an uncommon complication.^{760–764} There are rare associations with pregnancy,⁷⁶⁵ liver transplantation,⁷⁵⁵ healed herpes zoster,⁷⁶⁶ and port wine stain (nevus flammeus).^{767,768} Familial cases have also been described.⁷⁶⁹ Most cases do not regress, as do ‘strawberry nevi’ of infancy and childhood, but there are reports of partial or complete regression and the recurrence of lesions.^{748,765–773} Regression appears to be more common in congenital and early onset lesions.⁷⁴⁵

Treatment of large lesions can be difficult. Smaller lesions are often treated by surgical excision, but recurrences are common. Intralesional steroids, cryotherapy, and radiotherapy have not been successful.⁷⁵⁷ Subcutaneous IFN- α and the pulsed dye laser have given mixed results.⁷⁷⁴ One case was aggravated by the use of a long-pulsed Nd:YAG laser.⁷⁷⁵

Histopathology

There are multiple separated cellular lobules within the dermis and subcutis. Some lobules bulge the walls of dilated thin-walled vascular channels that are within the lobules or at their periphery. This sometimes gives the vessels a semilunar profile.⁶⁶⁸ These larger vessels have a distinct endothelial lining.

Each lobule is composed of cells with spindle-shaped and oval nuclei (Fig. 38.29). Mitotic figures may be seen, but there is no cellular atypia. Small capillary-sized vascular lumina are present in these areas. The morphology of the lobules resembles those seen in pyogenic granulomas. Hemosiderin may be present in the lesions; inflammation and

Figure 38.29 Acquired tufted angioma. The multiple vascular lobules are composed of spindle-shaped and polygonal cells. (H&E)

edema are not usually seen. Some authors have noted proliferation of eccrine sweat glands near the vascular lobules.^{765,776}

Tumor cells are positive for CD31 and CD34 but stain only weakly or not at all for factor VIII-related antigen.⁷⁷⁷ They are negative for GLUT-1.⁷⁷⁸ The dilated vessels partly stain with D2-40, but the proliferative capillaries are negative.⁷⁷⁸

Electron microscopy

Ultrastructural studies have confirmed cell-marker studies, which have shown that these lesions consist of endothelial cells and pericytes with small lumina.⁷⁴¹ In one study of ‘angioblastoma (Nakagawa)’, crystalloid inclusions were seen in endothelial cells.⁷⁴³

Differential diagnosis

The pattern of cellular nodules with a peripheral dilated channel superficially resembles Kaposi’s sarcoma, but the lobules lack the characteristic interlacing bundles of spindle cells and slit-like vessels, and they usually lack an inflammatory infiltrate with plasma cells. In endovascular papillary angioendothelioma of childhood, papillary processes lined by atypical endothelial cells protrude into vascular lumina. In Masson’s ‘vegetant intravascular hemangioendothelioma’, papular processes, composed of hyperplastic endothelium supported by fibrous stalks, are confined within vascular lumina.

GLOMUS TUMOR

Glomus tumors are neoplasms that resemble elements of the glomus apparatus in the skin.⁷⁷⁹ The glomus apparatus contains a central coiled canal, the Sucquet–Hoyer canal, which is lined by endothelium and several layers of glomus cells. Glomus tumors combine cells resembling glomus cells and vascular structures.

The glomus tumor is almost always a solitary, purple dermal nodule on the extremities, particularly the fingers and toes. It may have a subungual location and lie within a slight depression in the underlying phalanx. This variant usually presents in adults and occurs with an equal sex incidence. Glomus tumors can clinically present as longitudinal erythronychia; when this occurs, the tumor is usually localized to the nail matrix without extension down the nail bed, and therefore a longitudinal biopsy is generally unnecessary in such cases.⁷⁸⁰ The tumors are almost always painful. The pain varies in intensity but may be severe and paroxysmal, and it may occur spontaneously or be

induced by pressure or cold. Rarely, a small cluster of tumors may occur.⁷⁸¹ Of the 56 cases of extradigital glomus tumor reviewed at the Mayo Clinic, only 1 case involved an extracutaneous site (the trachea).⁷⁸² The forearm and knee were the most common extradigital sites of involvement.⁷⁸² An association of multiple glomus tumors with segmental neurofibromatosis has been reported.⁷⁸³

Although they almost always occur in the skin, rare lesions have been reported at other sites, including the deep soft tissues,⁷⁸⁴ bone,^{785,786} vagina,⁷⁸⁷ trachea,⁷⁸⁸ lung,⁷⁸⁹ gastrointestinal tract,^{790,791} oral cavity,⁷⁹² nasal cavity,^{793,794} within veins,^{768,795} and in cutaneous nerves.^{796,797} There is no evidence of an aggressive clinical behavior with the intravascular lesions.⁷⁹⁸ It is uncertain how many of these extracutaneous cases would now be reclassified as GVMs. Most of the cases reported in the past as disseminated or regional glomus tumors would now be regarded as GVMs. They are considered with the vascular malformations on page 1074.

Benign lesions are occasionally locally infiltrative;⁷⁹⁹ they may recur after removal.⁸⁰⁰ Digital glomus tumors are more likely to recur if they are flesh-colored or arise within the nail matrix.⁸⁰¹ Atypical glomus tumors are discussed further later.

Histopathology

The glomus tumor proper is a well-circumscribed or encapsulated dermal tumor that may extend into the subcutis. It is composed of solid aggregates of glomus cells surrounding inconspicuous vessels. Glomus cells are rounded, regular cells with eosinophilic cytoplasm and darkly staining round to oval nuclei (Fig. 38.30). Tumor cells and vessels are embedded in a fibrous stroma. Some tumors contain large amounts of myxoid stroma (Fig. 38.31).⁸⁰² The tumor matrix contains small unmyelinated nerve fibers and mast cells. The uniformity of the cells and their lack of pleomorphism are features of these tumors. Oncocytic and epithelioid variants have been described.^{803,804} The latter are composed of large polygonal to spindle-shaped cells with abundant eosinophilic cytoplasm and large irregular nuclei. The cytological atypia is thought to represent cellular senescence.⁸⁰⁴ The term ‘*symplastic glomus tumor*’ has been used for these lesions, which have a high nuclear grade in the absence of any other malignant features.^{164,805} Another variant is the *infiltrative glomus tumor*, characterized by an infiltrative growth pattern at the periphery of the lesion.⁸⁰⁶ Some of these lesions have been regarded in the past as malignant glomus tumors. This category of infiltrative glomus tumor is not included in

the classification proposed by Folpe *et al.*¹⁶⁴ Extensive *glomus cell hyperplasia* has been reported in the vicinity of a cluster of multiple glomus tumors.⁷⁸¹

Immunohistochemical techniques have demonstrated vimentin, muscle-specific actin and α -smooth muscle actin in the cytoplasm; laminin and type IV collagen are present in the basal lamina-like material.^{140,807,808} The cells lack the cell markers of endothelial cells (CD31 and CD34). The absence of desmin from the tumor cells is a feature shared with some cells of vascular smooth muscle.^{140,808}

Multiple nerve fibers containing substance P have been identified within solitary glomus tumors.⁸⁰⁹ Substance P is known to be a sensory afferent neurotransmitter for mediating painful stimuli.

Nail plate dermoscopy of subungual glomus tumors can be difficult because vascular structures may be difficult to visualize. Maehara *et al.* recommended intraoperative nail matrix and nail bed dermoscopy following careful nail plate avulsion to enhance visualization of the tumor and better define surgical margins.⁸¹⁰

Electron microscopy

The tumor cells show similar ultrastructural features to smooth muscle cells. Each cell is surrounded by a basal lamina and contains cytoplasmic intermediate filaments, microfilaments, pinocytotic vesicles, and dense bodies in the cytoplasm and adjacent to the plasma membrane.^{140,808}

Differential diagnosis

A relatively common differential diagnostic problem related to glomus tumors is the need to separate them from nodular eccrine hidradenomas (acrospiromas), which can appear quite similar on low-power inspection. This task is most easily accomplished by immunostaining for actin, which is positive in glomus tumors, and keratin, which is seen in hidradenomas.⁸¹¹

Glomus coccygeum

The glomus coccygeum is a vestigial structure sometimes found in skin and deeper specimens removed from the lumbosacral region. It is a heavily innervated modified arteriovenous anastomosis akin to the Sucquet–Hoyer canals of the distal fingers and toes.⁸¹² Their function at this site is unknown.

Figure 38.30 Glomus tumor. There are sheets of glomus cells and a few blood vessels. (H&E)

Figure 38.31 Glomus tumor. The stroma between some of the nests of glomus cells contains mucin. (H&E)

They are usually an incidental finding in resected specimens of a pilonidal sinus.^{812,813} They average only 1 mm in diameter, although they are reported to reach 5 mm in size.^{812,814}

Histopathology

It is composed of clusters and nests of small to medium-sized epithelioid cells intimately associated with small vascular channels. There is a superficial resemblance to a glomus tumor or paraganglioma.⁸¹⁴ Small nerve bundles are present in the stroma. A complex hamartoma composed of elements resembling a neurovascular hamartoma, a lipomatous hamartoma, and glomus bodies has been reported in the intergluteal region.⁸¹⁵

The cells express muscle-specific actin, vimentin, and neuron-specific enolase. The small nerves are highlighted by an S100 preparation. The epithelioid cells are weakly positive for smooth muscle actin, and they are negative for desmin, synaptophysin, chromogranin, melan-A, EMA, cytokeratin, endothelial markers, and brachyury (a transcription factor whose expression is considered diagnostic for chordoma).⁸¹⁶ The endothelial cells of the vessels stain for CD31,⁸¹² CD34, and factor VIII; they are negative for podoplanin.⁸¹⁶

ERUPTIVE PSEUDOANGIOMATOSIS

Prose and colleagues reported three children who, during an apparent viral illness, developed angiomatous papules that resolved spontaneously.⁸¹⁷ Other similar cases have been reported.⁸¹⁸ A subsequent case has been characterized by spontaneous healing in 2 weeks, followed by a recurrent eruption 3 weeks later, which again healed.⁸¹⁹ Another report described an outbreak of the condition in nine adult patients in a mental institution.⁸²⁰ Subsequent cases have not always been associated with an obvious viral illness, suggesting multiple etiologies.^{819,821,822} They have been associated with graft-versus-host disease,^{823,824} cyclosporine, combination chemotherapy for Hodgkin's disease (doxorubicin, bleomycin, vincristine, etoposide, cyclophosphamide, and prednisone),⁸²⁵ and insect bites.⁸²⁶

The pathogenesis of these lesions is unknown, but it may involve an increase in vascular growth factors.⁸²³ Because the lesions usually resolve spontaneously, no treatment is necessary. Cases associated with graft-versus-host disease are larger and probably a different (persistent) entity (eruptive angiomatosis).^{823,824}

Histopathology

The lesions are composed of dilated blood vessels in the upper dermis, lined by plump 'hobnail' endothelial cells.⁸¹⁷ The endothelial cells have not always been enlarged.⁸²¹ A mild perivascular infiltrate of lymphocytes has been present in most cases.^{820,827} Intravascular neutrophils were frequently identified in the cases of Kim *et al.* and are considered helpful in the diagnosis of this condition; intravascular eosinophils are less frequently identified.⁸²⁸

The lesions associated with graft-versus-host disease are angiomatous in nature with large, dilated vascular spaces. They bear no resemblance to this entity.^{823,824} In contradistinction, they have been called **eruptive angiomatosis**.

PAPULAR ANGIOPLASIA

The two recorded cases of papular angioplasia were in elderly patients who presented with vascular papules of the face and scalp in which the dermal vascular proliferation contained atypical bizarre endothelial cells.⁸²⁹ The lesions, which were termed 'papular angioplasia', were thought of as a 'pseudomalignancy'. Their relationship to pyogenic granuloma and angiolymphoid hyperplasia is uncertain.

MULTINUCLEATE CELL ANGIOHISTIOCYTOMA

Multinucleate cell angiohistiocytoma was first described by Smith and Wilson Jones.⁸³⁰ It is characterized by grouped, red to violet papules that may resemble Kaposi's sarcoma;⁸³¹ almost all reported cases have been in females older than age 40 years.^{831–834} Cases in males have been reported.⁸³⁵ The legs, particularly the calves and thighs, are most commonly involved;⁸³⁶ the hands are the second most common site.^{831,833} Occasional cases have occurred on the chest⁸³¹ and face.^{831,837,838} Generalized eruptive lesions have been reported in a pregnant patient⁸³⁹ and in several cases involving males.^{840,841} Papules develop over several months and then growth ceases. Some lesions are pruritic.⁸³⁶ Spontaneous resolution does not often occur. The etiology is not known; HHV-8 has not been detected.⁸⁴² Pérez *et al.* have regarded it as a variant of dermatofibroma,⁸³⁶ a view also expressed by Puig *et al.*⁸⁴³ In one case, the lesions were successfully treated by cryosurgery.⁸³⁶ Surgery and argon laser have also been used.

Histopathology⁸³¹

It is not clear whether multinucleate cell angiohistiocytoma is primarily a vascular or a stromal cell tumor. The two main components are increased numbers of ectatic or narrow vessels in the upper and mid dermis and large angulated multinucleate cells (Fig. 38.32). In addition, there is a less conspicuous component of 'fibrohistiocytic' (dendritic) cells scattered between the collagen bundles in a horizontal pattern.⁸³⁵ These cells express factor XIIIa.⁸⁴³ The vessels are small venules and capillaries, lined by endothelial cells with prominent nuclei. Angulated multinucleate cells have 3–10 nuclei arranged in a ring or clumped together; they are basophilic. These large cells stain with vimentin but not with macrophage markers (Mac387, CD68, and lysozyme), CD31, CD34, S100, or factor XIIIa.⁸⁴² A recent paper did show staining of these multinucleate cells with factor XIIIa.⁸³⁶ Other interstitial cells appear to be indeterminate or Langerhans cells (CD1a⁺) or macrophages (lysozyme⁺, CD68⁺, and Mac387⁺).^{831,837} Estrogen receptor α is overexpressed in multinucleate cell angiohistiocytoma, particularly in interstitial spindle cells and those surrounding the vascular component. This is in contrast to dermatofibroma, in which only a few scattered spindle cells, sebocytes, and perifollicular mesenchymal cells are positive, and it suggests a different pathogenesis for multinucleate cell angiohistiocytoma.⁸⁴⁴ Discrete foci of

Figure 38.32 Multinucleate cell angiohistiocytoma. There are atypical cells and an increase in small vessels in the papillary dermis. (H&E)

inflammatory cells are also present. The ultrastructural features have also been described.⁸³²

REACTIVE ANGIOENDOTHELIOMATOSIS

Reactive angioendotheliomatosis (reactive angiomatosis) is a cutaneous vascular proliferation that presents as infiltrated, red-to-blue patches and plaques, often with purpura. Necrosis and ulceration may sometimes develop.⁸⁴⁵ The lesions may occur at any body site. They measure from 1 to 3 cm or more in diameter. This vascular proliferation may be associated with a variety of conditions, many of which have in common luminal obstruction by thrombi or abnormal proteins. It may occur in association with chronic disseminated intravascular coagulation (DIC),⁸⁴⁶ cryoglobulinemia,⁸⁴⁷ infections, paraproteinemia with myelomatosis, leukemia,⁸⁴⁸ dermal amyloid angiopathy,⁸⁴⁹ intravascular immunoglobulin deposits associated with a monoclonal gammopathy, the antiphospholipid syndrome,⁸⁵⁰ the lupus anticoagulant, sarcoidosis,⁸⁵¹ systemic diseases,⁸⁵² hepatopathy, and arteriovenous fistulae used for hemodialysis.^{845,853-855} Some patients are iatrogenically immunosuppressed.⁸⁵² A similar lesion has been reported overlying an implanted nickel nail for delayed union of a fracture and also as an idiopathic phenomenon in a child.^{856,857} The lesions usually resolve after the withdrawal or the cure of the initiating process. It must be distinguished from malignant angioendotheliomatosis, an angiotropic lymphoma, and from the intravascular simulant seen in patients with rheumatoid arthritis and variously called reactive angioendotheliomatosis, cutaneous histiocytic lymphangitis, and intravascular histiocytosis (see p. 1161),⁸⁵⁸ although a comparatively recent paper suggested that reactive angioendotheliomatosis may be intravascular histiocytosis.⁸⁵⁹

In 2003, Rongioletti and Rebora suggested the concept of the '**cutaneous reactive angiomatoses**' characterized histologically by different patterns of intravascular or extravascular lobular or diffuse hyperplasia of endothelial cells, pericytes, and sometimes histiocytes.⁸⁶⁰ They included the following conditions under this umbrella term:

- Reactive angioendotheliomatosis
- Diffuse dermal angiomatosis
- Acroangiodermatitis (pseudo-Kaposi's sarcoma) – see below
- Reactive intravascular histiocytosis – see page 1161
- Glomeruloid reactive angioendotheliomatosis (with cold agglutinins)
- Angiopericytomatosis (angiomatosis with cryoproteins).

The latter condition, described by LeBoit *et al.*⁸⁴⁷ and included here as an example of reactive angioendotheliomatosis, actually had a periluminal proliferation of pericytes and intraluminal thrombi. The case referred to as glomeruloid reactive angioendotheliomatosis had lobular proliferations of dilated vessels filled with clusters of closely spaced capillaries with a glomeruloid pattern.⁸⁶⁰

Histopathology

Reactive angioendotheliomatosis is characterized by a benign intraluminal proliferation of endothelial cells that may occlude the vascular lumina. The vessels are dilated (Fig. 38.33). A proliferation of vessels also occurs that may have a diffuse, lobular, or mixed pattern.⁸⁵² Sometimes the proliferated endothelial cells produce a glomeruloid appearance. The cells may be large and mildly atypical, but they are not malignant. Thrombi and protein deposits are sometimes found. The dermis may show reactive (fasciitis-like) alterations.⁸⁵² There is usually only minimal inflammation, if any. The cells express CD31, CD34, and factor VIII-related antigen. In one case, the intraluminal cells stained with CD68 – a feature seen in intravascular histiocytosis.⁸⁵⁹

Granular deposits of IgA, IgM, and complement were found around the vessels and at the dermal-epidermal junction in two cases.⁸⁶¹

Figure 38.33 Reactive angioendotheliomatosis. In this example, intraluminal proliferation of endothelial cells is apparent. (H&E)

Diffuse dermal angiomatosis

Diffuse dermal angiomatosis is a variant of reactive angioendotheliomatosis associated with severe atherosclerosis causing vascular narrowing.⁸⁶²⁻⁸⁶⁴ Clinically, there are poorly circumscribed, violaceous and livedoid plaques with frequent ulceration.⁸⁶⁵ They may be painful. Lesions are usually on the lower legs. Several cases have been reported on the breast.^{861,866-868} The breasts are usually pendulous, and there may be a further factor, such as heavy smoking, anticardiolipin antibodies, or subclavian artery stenosis.^{868,869} The term diffuse dermal angiomatosis is a misnomer for these cases, and segmental or localized (reactive) angioendotheliomatosis would be a better term.⁸⁷⁰ Lesions resolve completely following revascularization of the limb.⁸⁶⁵ Interestingly, two cases of vascular proliferation have been reported in the skin distal to an arteriovenous fistula made for hemodialysis: one case resembled reactive angioendotheliomatosis and the other diffuse dermal angiomatosis, indicating the close relationship between these two entities.⁸⁵⁴ Examples of diffuse dermal angiomatosis have been associated with calciphylaxis⁸⁷¹ and cutis marmorata telangiectatica congenita.⁸⁷²

Cases reported on the breast have responded to isotretinoin,^{867,868} although in one of these cases correction of a subclavian artery occlusion was also carried out.⁸⁶⁸ Reduction mammoplasty was successful in a patient with macromastia.⁸⁶⁶

Histopathology

In diffuse dermal angiomatosis, the hyperplastic endothelial cells, sometimes spindled,⁸⁶⁹ diffusely infiltrate the papillary and reticular dermis, sometimes forming small vascular lumina.^{862,863} The cells stain with CD31 and CD34.⁸⁷³ This contrasts with the intravascular proliferation seen in reactive angioendotheliomatosis.

ACROANGIODERMATITIS

Acroangiodermatitis (pseudo-Kaposi's sarcoma) is a vasoproliferative disorder that resembles Kaposi's sarcoma both clinically and histologically.^{368,874-876} The lesions arise in a background of increased venous pressure due to chronic venous insufficiency,^{877,878} paralysis of a limb,⁸⁷⁹ congenital arteriovenous malformation,⁸⁸⁰⁻⁸⁸³ Klippel-Trenaunay

syndrome,^{884,885} activated protein C resistance,⁸⁸⁶ or acquired arteriovenous fistula.^{887,888} Acroangiokeratosis has also been reported in an above-knee amputation stump.⁸⁸⁹⁻⁸⁹² Several recently reported cases involved the use of a suction socket prosthesis in leg amputees.^{893,894} The majority occur on the lower part of the legs and on the feet; in cases associated with arteriovenous malformations, they are found over the site of the malformation. In most cases affecting the legs, there is also stasis dermatitis. The lesions consist of purple papules and nodules with variable surface scale.⁸⁹⁵ Those cases associated with venous insufficiency or paralysis of the legs have a characteristic distribution, occupying a triangular region on the extensor surface of the foot and toes, with the most prominent lesions on the first and second toes.⁸⁷⁷ Lesions may be unilateral or bilateral, depending on the cause.⁸⁹⁶ There is a male preponderance.⁸⁹⁷

Rongioletti and Rebora included acroangiokeratosis with the cutaneous reactive angiomatoses (discussed previously).⁸⁶⁰ Ischemia with an increase in VEGF underlies many of these conditions. In acroangiokeratosis, some of the predisposing factors result in the arteriovenous steal syndrome with distal ischemia and a localized increase in VEGF.⁸⁸⁵ The treatment is very dependent on the underlying cause.⁸⁷⁶

Histopathology^{898,899}

The papules and nodules consist of a proliferation of small dilated vessels in an edematous dermis (Fig. 38.34). The vessels have fairly regular profiles and lack the jagged outline and 'promontory' sign seen in early lesions of Kaposi's sarcoma.⁸⁹⁸ Plump endothelial cells, without atypia, line the vessels. The cells are positive for CD31 and CD34,⁹⁰⁰ but they are negative for HHV-8 and D2-40.⁹⁰¹ The perivascular cells do not stain for CD34.⁸⁸⁵ A slight perivascular fibroblastic proliferation is also seen but is not marked. Some lesions show nodular collections of vessels with narrow lumina.⁸⁹⁹ Extravasated red blood cells, hemosiderin, and a variable round-cell infiltrate are seen around the vascular proliferation. Plasma cells are usually not present. Mast cells may be numerous.⁸⁸⁵ The overlying epidermis may show hyperkeratosis.

MISCELLANEOUS LESIONS

Rarely, patients with chronic DIC develop plaques of purplish discoloration that on biopsy show an apparent increase in small vessels arranged in leashes in the dermis and subcutaneous fat (Fig. 38.35). The vessel proliferation represents organization of thrombosed vessels.⁸⁴⁶ A similar 'angiomatosis' has been reported in cryoproteinemia.⁸⁴⁷

PENILE MYOINTIMOMA

The penile myointimoma is a rare myointimal proliferation described by Fetsch *et al.* in 2000.⁹⁰² It affects the corpus spongiosum of the glans penis or corona. It affects all ages, including children. The lesions average 1 cm in diameter.

Histopathology

There is a multinodular and plexiform intravascular proliferation of spindle-shaped myofibroblasts with elongate cells set in a fibromyxoid stroma. A meshwork of elastic fibers surrounds the individual tumor nodules.⁹⁰³ It has some similarities to intravascular fasciitis.⁹⁰⁴

The spindle cells are reactive for smooth muscle actin, muscle-specific actin, and calponin. There may be a collar of desmin positivity at the periphery of the lesion.⁹⁰⁴ The endothelial cells express CD31 and CD34.⁹⁰²

Figure 38.34 (A) Acro-angiokeratosis. (B) There is a proliferation of small vessels in an edematous dermis. Fibroblasts are also increased. (H&E)

INTRAVASCULAR PAPILLARY ENDOTHELIAL HYPERPLASIA

Pierre Masson first described this vascular proliferation in hemorrhoidal veins; he regarded it as a neoplastic process. He named it 'hémangioendothéliome végétant intravasculaire'.⁹⁰⁵ Its importance lies in its

Figure 38.35 Vascular proliferation in a patient with chronic disseminated intravascular coagulation (DIC). Thrombi are present in some of the vessels. (H&E)

Figure 38.36 Intravascular papillary endothelial hyperplasia. Vascular channels are present within the lumen of a dilated vein. (H&E)

histological resemblance to angiosarcoma: the name ‘Masson’s pseudoangiosarcoma’ has also been proposed.⁹⁰⁶⁻⁹¹⁰ The condition is now generally regarded as an unusual pattern of organization of a thrombus within a vein^{368,907,909,911} or within one or more of the component vessels of various vascular abnormalities. These include cavernous hemangiomas,^{906,908} pyogenic granulomas,^{699,906,912} and lymphangiomas.⁹¹³ Organizing hematomas of soft tissues may also show this pattern.⁹¹⁴ In most cases, there is a single lesion, but multiple lesions have also been described.⁹¹⁵ They usually present clinically as firm, sometimes painful nodules that appear blue or purple through the overlying skin.⁹⁰⁹ On section, typical lesions appear encapsulated and cystic; they contain variable amounts of thrombus. Although lesions can occur at any site, including the tongue,⁹¹⁰ they are most commonly found on the fingers, head and neck, and trunk.^{906,909,916} There is a female predominance in most series.^{906,909} Local excision is curative.

A history of trauma is sometimes present. The lesion is thought to result from the liberation of vascular growth factors in the area.⁹¹⁷ Expression of hypoxia-induced factor 1 α (HIF-1 α) and VEGF has been found to correlate with thrombus remodeling in intravascular papillary endothelial hyperplasia.⁹¹⁸

Histopathology

In most examples, the proliferation is limited to the lumen of an identifiable vein or vessel in a vascular abnormality (Fig. 38.36). Occasionally, there is only a fibrous capsule lacking definite features of a vessel wall. Rarely, the proliferation extends outside the lumen, possibly due to rupture of the wall of the vessel. Masses of papillary processes are present within the lumen, and they are almost always associated with some thrombus. Each papillary frond is covered by a single layer of plump endothelial cells. Mitotic figures may be present, but they are never frequent. There is no multilayering of the cells, and solid cellular areas, cellular tufts, atypia, and necrosis are not usually evident; however, Renshaw and Rosai described severe cytological atypia in lesions from the lip.⁹¹⁹ The core of the papillae consists of fibrin or collagenous connective tissue, depending on the stage of organization.

Electron microscopy

Electron microscopy confirms the endothelial nature of the cells and demonstrates that they lie on a basement membrane, outside of which are pericytes.⁹²⁰

BACILLARY ANGIOMATOSIS

Bacillary angiomatosis was first described by Stoler *et al.* in 1983.⁹²¹ It is a systemic disorder that was first identified because of cutaneous lesions resembling Kaposi’s sarcoma.⁹²² Bacillary angiomatosis is caused by two closely related gram-negative coccobacilli, *Bartonella (Rochalimaea) henselae* and *Bartonella (Rochalimaea) quintana*.⁹²³⁻⁹²⁷ *Bartonella henselae* is also a common cause of cat-scratch disease; it has also been associated with a bacteremic syndrome and peliosis hepatis.⁹²³ *Bartonella quintana* is the causative agent of trench fever.

Bacillary angiomatosis occurs primarily in those with HIV infection,^{922,928-930} but it has also been reported in organ transplant recipients;⁹²³ in patients with leukemia,^{931,932} including chronic lymphocytic leukemia treated with chemotherapy;⁹³³ in patients on systemic steroid therapy;⁹³⁴ and even in immunocompetent individuals, including children.⁹³⁵⁻⁹⁴⁰ Up to two-thirds of cases are associated with exposure to cats; lesions sometimes follow a bite or scratch.⁹⁴¹ Cutaneous tumors are usually multiple and take the form of pyogenic granuloma-like lesions, subcutaneous nodules, or, uncommonly, hyperpigmented indurated plaques, with the last form occurring particularly in black people.⁹⁴² Leg ulcers may follow scratches from cats.⁹⁴³ Pyogenic granuloma-like lesions are dusky-red in color, often pedunculated, frequently bleed, and may be mildly tender. They resemble the lesions of verruga peruana. Spontaneous regression sometimes occurs. The lesions of bacillary angiomatosis also occur on respiratory and gastrointestinal tract mucosa and in the heart, liver, spleen, bone marrow, muscle, soft tissue, and brain. Patients often have constitutional symptoms, particularly when extracutaneous lesions are present.⁹²³ An association with hemophagocytic syndrome has been rarely reported.⁹⁴⁴ Angiomatous and papillomatous lesions of the oral cavity have been reported from *Bartonella* infections associated with allogeneic bone marrow transplantation and oral graft-versus-host disease.⁹⁴⁵ They are a related entity.

Although bacillary angiomatosis is treatable and curable, it may be life-threatening if not addressed.⁹⁴⁰ For example, a case of fatal bacillary angiomatosis occurred during the immune restoration phase in an HIV⁺ patient.⁹⁴⁶ It usually responds to treatment with erythromycin, ciprofloxacin, third-generation cephalosporins, tetracyclines, or aminoglycosides. Erythromycin is the treatment of choice.⁹⁴³

Figure 38.37 (A) Bacillary angiomatosis in a patient with AIDS. (B) Neutrophils, nuclear dust, and a clump of granular material (representing bacteria) are present in the stroma between the small vascular channels. (H&E) (Microscopic slide kindly provided by Dr Philip LeBoit, Department of Pathology and Dermatology, University of California, San Francisco.)

Histopathology^{928,942}

Superficial lesions are characterized by small round blood vessels in an edematous stroma. Deeper lesions are more cellular and compact. In both forms, blood vessels are lined by plump, epithelioid endothelial cells. A background inflammatory cell infiltrate of lymphocytes, histiocytes, and neutrophils is also present. Neutrophils are plentiful in deeper lesions. A peripheral collarette and ulceration are seen in superficial lesions (Fig. 38.37). Pseudoepitheliomatous hyperplasia is a rare event.⁹⁴⁷ Organisms are seen as clumps of amphophilic granular material, particularly near neutrophils; they are readily demonstrated by a Giemsa, Warthin–Starry, or Grocott methenamine silver stain.^{928,948} Immunohistochemical techniques and polymerase chain reaction (PCR)-based methods have also been used to identify organisms.^{926,949} Ultrastructurally, organisms are seen in the interstitium of lesions and are pleomorphic structures with a trilaminar wall and coarsely granular cytoplasm.⁹⁵⁰

Differential diagnosis

Bacillary angiomatosis is usually easy to differentiate from Kaposi's sarcoma because of the presence of epithelioid endothelial cells,

neutrophils, and organisms in the former and spindle cells and slit-like vessels in the latter. The two conditions may occur concurrently,⁹⁵¹ but bacillary angiomatosis is much less common than Kaposi's sarcoma in patients with AIDS. Neutrophils are confined to the surface of ulcerated lesions of pyogenic granuloma; this lesion is usually more obviously lobulated. Organisms are not seen in pyogenic granuloma.

VERRUGA PERUANA

The skin lesion of the eruptive phase of Carrión's disease (bartonelosis), caused by *Bartonella bacilliformis*, is known as verruga peruana (Peruvian wart).^{952,953} Carrión's disease is endemic at altitudes between 800 and 2500 m in areas of Peru, Ecuador, and Colombia. Multiple, miliary superficial hemangioma-like lesions or larger, deeper, sometimes ulcerated lesions occur in this condition. They resolve spontaneously over weeks to months.^{952,953} A new causative agent, currently termed *Candidatus Bartonella ancashi*, has been described by Mullins and colleagues.^{954,955}

Histopathology

Superficial lesions consist of a proliferation of capillary-like vessels in the papillary dermis, with the formation of a collarette. There is an associated inflammatory infiltrate composed of lymphocytes and plasma cells. In nodular lesions, there is a multilobular proliferation or more solid aggregation of cells in the dermis and sometimes also in the subcutis. Vascular lumina are fewer and smaller. The 'tumor cells' are large and epithelioid; groups of them are surrounded by a reticulin network. Mitotic figures are frequent. A spindle cell element is occasionally seen and may make distinction from Kaposi's sarcoma extremely difficult. Immunohistochemical studies have identified these cells as endothelial in nature because they are positive for both factor VIII-associated antigen and *Ulex europaeus*-1 lectin.⁹⁵² In regressing lesions, there is involution and necrosis of the vascular elements, associated with a heavy infiltrate of lymphocytes, histiocytes, and neutrophils. There is subsequent fibrosis.

The causative organism is not seen by light microscopy but may be found on ultrastructural examination, predominantly in an extracellular location but occasionally in phagosomes.⁹⁵² Rocha Lima inclusions, consisting of conglomerates of apparently intracellular cytoplasmic granules that are colored red by Romanowsky–Giemsa stains, may be seen within the endothelial cells. Ultrastructurally, these appear to consist of phagosomes containing organisms and interstitial matrix-like material as well as a labyrinth of cisternal channels with similar contents.⁹⁵²

LYMPHANGIOENDOTHELIOMA (ACQUIRED PROGRESSIVE LYMPHANGIOMA)

Lymphangioendothelioma (acquired progressive lymphangioma) is a rare, benign vascular proliferative lesion of lymphatic origin.^{956–958} It has not always been accepted as being a lymphatic lesion.⁹⁵⁹ The cases reported recently as *multifocal lymphangioendotheliomatosis* were characterized by hundreds of congenital red-brown skin plaques as large as a few centimeters, with similar lesions throughout the gastrointestinal tract.⁹⁶⁰ The thrombocytopenia that accompanied these cases was due to platelet trapping in the channels. The vessels expressed the lymphatic marker LYVE-1.⁹⁶⁰ This term has now been proposed as an alternative name for widespread lesions.⁹⁵⁸ There are histological similarities to cutaneous angiosarcoma, but the course of the reported cases has been benign. The lesion presents as an erythematous patch or plaque that gradually enlarges, often over many years.⁹⁶¹ Multifocal lesions with thrombocytopenia occur, as already mentioned. There is no site predilection, with cases having been reported on the abdomen,

Figure 38.38 Lymphangioendothelioma (acquired progressive lymphangioma). In this image, thin-walled, interconnecting vessels are oriented horizontally in the superficial dermis. The endothelial cells are plump and display nuclear hyperchromasia. (H&E)

leg, arm, and head.⁹⁶¹ Most tumors reported have been in adults,⁹¹⁹ but this lesion may also arise in children,^{956,959,961,962} rarely, it is congenital.^{963,964} It has been associated with previous femoral arteriography,⁹⁶⁵ trauma to a ‘vascular birthmark’, a tick bite, and radiotherapy.^{966–968} One case resolved spontaneously.⁹⁶⁹

Histopathology⁹¹⁹

The main feature is the presence of thin-walled interconnecting vascular channels at various levels of the dermis or subcutis. These vessels tend to be arranged horizontally, particularly in the upper dermis. Vessels are smaller, more irregular, angular and cleft-like at deeper levels, and they ‘dissect’ the dermal collagen bundles. The vessels are lined by flat to plump endothelial cells with some focal nuclear hyperchromasia and crowding (Fig. 38.38). No frank atypia or mitotic figures have been reported. No intraluminal cell clumps are seen. Vessels contain proteinaceous material, a few red blood cells, or are empty. The vessels are usually surrounded by chronic inflammatory cells, often including a few plasma cells.⁹⁷⁰

Immunohistochemical studies are conflicting: endothelial cells have been reported as staining positively or negatively for factor VIII-related antigen and *Ulex europaeus*-1 lectin and positively for CD34 and CD31.^{967,971} The cells stain strongly with the lymphatic endothelial marker D2-40.⁹⁷² Additional recent reports support this result because they have shown positivity for D2-40, LYVE-1, and/or Prox1 (a marker for a lymphatic endothelial nuclear transcription factor).^{973,974} They are negative for HHV-8.⁹⁷⁵ Basement membrane has been shown to be present by positive staining for type IV collagen and laminin. It has been absent by electron microscopy. A smooth muscle component has also been demonstrated focally, around the vascular spaces.^{919,959,963,965,966,969} There have been variable results with staining for WT1: positive in one case of giant benign lymphangioendothelioma⁹⁷³ and negative in a recent series of four cases.⁹⁷⁴ Further studies are necessary to determine if these lesions are neoplastic or representative of a type of lymphatic vascular malformation.

Differential diagnosis

Histologically, this lesion may mimic angiosarcoma and patch-stage Kaposi’s sarcoma. The distinction from well-differentiated angiosar-

coma, particularly from the D2-40-positive cases, can be very difficult; usually there is more cellular atypia or cellular tufts in angiosarcoma. The long clinical history and the site of the lesion may be helpful. The face and scalp are the usual sites for cutaneous angiosarcoma. Early Kaposi’s sarcoma may be impossible to distinguish from lymphangioendothelioma, but in the former there may be red blood cells, hemosiderin, and an inflammatory cell infiltrate that includes plasma cells. Inflammation is minimal in lymphangioendothelioma.⁹¹⁹ The patch stage of Kaposi’s sarcoma is usually seen in AIDS-related cases, and lesions are often multiple. Although it is also D2-40 positive, Kaposi’s sarcoma stains for HHV-8, which does not occur in lymphangioendothelioma.

ATYPICAL VASCULAR LESIONS (BENIGN LYMPHANGIOMATOUS PAPULES OF THE SKIN (BLAP))

The lesions reported as **benign lymphangiomatous papules of the skin (BLAP)** are related lesions occurring at sites of radiotherapy.^{976,977} Other vascular tumors may occur in irradiated skin.^{978–981} In a review of 32 cases, Patton *et al.* used the term ‘**atypical vascular lesions**’ (AVLs) in preference to BLAP for these cases.⁹⁸⁰ A similar view was taken by Mattoch *et al.*, who acknowledged the close clinical and histopathological relationship of these lesions to angiosarcoma.⁹⁷⁹ Five of their cases were subsequently shown to have angiosarcoma, indicating that all such cases should have wide local excision with clinical follow-up.⁹⁷⁹ Unfortunately, none of these cases was stained with D2-40. Brenn and Fletcher also abandoned the term BLAP for these cases and referred to them as AVLs (see p. 1108).⁹⁸² Further follow-up of the benign vascular proliferations in irradiated skin reported by Requena *et al.* in 2002 would also be instructive.⁹⁸¹ They have also been reported in association with an untreated ovarian fibroma.⁹⁸³ The lesions almost disappeared after removal of the tumor. The lesions present as solitary or multiple papules or vesicles. Disruption of the lymphatic drainage is the probable pathogenesis of these acquired papules.⁹⁸³

A significant advance in our understanding of these lesions occurred with the discovery, by Guo *et al.*, that consistent *MYC* gene amplification is found in radiation-induced angiosarcoma but not in radiation-associated atypical vascular lesions (see later).⁹⁸⁴

Histopathology

Atypical vascular lesions (BLAP) consist of markedly dilated vascular spaces in the upper dermis exhibiting atypical features that include endothelial cells with plump or flattened nuclei and numerous small papillary projections. As the lesions descend into the deeper dermis, the spaces become smaller and their lumina irregular, focally dissecting the collagen.⁹⁷⁶ Some of the postirradiation cases reported as angiosarcomas in the past may be this benign entity.⁹⁷⁸ The endothelial cells are positive for *Ulex europaeus*-1 lectin and weakly positive for CD31, CD34, and factor VIII-related antigen. They stain with the lymphatic endothelial marker D2-40.⁹⁸⁵

Guo *et al.* found that the regulator gene *MYC* is consistently amplified in secondary (postirradiation) angiosarcomas but not in atypical vascular lesions or in other radiation-induced sarcomas. Co-amplification of *FLT4* (which encodes VEGFR3) was found in one-fourth of secondary angiosarcoma lesions.⁹⁸⁴ This suggests that *MYC* amplification can be used as a molecular diagnostic tool to distinguish secondary angiosarcoma from atypical vascular lesions. That conclusion was supported by a study by Mentzel *et al.* using fluorescence *in situ* hybridization analysis. In addition, the latter authors found strong nuclear immunohistochemical staining for *MYC* and prox-1 in postirradiation angiosarcoma, whereas cases of postirradiation atypical vascular lesions were negative for *MYC* and showed only focally positive staining for

prox-1.⁹⁸⁶ It would be worthwhile to evaluate the previously reported examples of atypical vascular lesions that were subsequently shown to be angiosarcoma using these molecular and immunohistochemical methods.

Differential diagnosis

Cutaneous angiosarcomas are usually larger than atypical vascular lesions. Angiosarcomas display significant cytologic atypia with enlarged cells, prominent nucleoli, mitotic activity, endothelial hyperplasia with multilayering, and subcutaneous infiltration. Features more indicative of atypical vascular lesions include good circumscription; endothelial cells with hyperchromatic, otherwise bland-appearing nuclei; protrusions of stroma into vascular lumina; and chronic inflammatory infiltrates. However, there are clearly lesions in which the features overlap or are inconclusive. In these circumstances, the finding of *MYC* amplification supports a diagnosis of postirradiation angiosarcoma. Hobnail hemangiomas arise on the trunk or extremities in nonirradiated skin as pigmented, flat, or exophytic lesions. Microscopically, there are superficial dilated vessels and hemosiderin deposition but a lack of hyperchromatic endothelial cells. Kaposi's sarcoma arises in a different clinical setting, has atypical spindle cells, and displays nuclear HHV-8 positivity with immunohistochemistry.⁹⁸⁷

TUMORS WITH VARIABLE OR UNCERTAIN BEHAVIOR

This category of vascular tumors has evoked considerable controversy, particularly the use of the term 'borderline' malignancy to describe the behavior of some tumors in this group.⁹⁸⁸ The term 'hemangioendothelioma' has also attracted criticism because it has been applied to both benign and malignant vascular tumors.⁵⁵⁷ While acknowledging the validity of this comment, the designations originally reported are used here to avoid confusion.

The following tumors have a variable behavior and outcome:

- Kaposi's sarcoma
- Hemangiopericytoma
- Kaposiform hemangioendothelioma
- Endovascular papillary angioendothelioma of childhood.

KAPOSI'S SARCOMA

Kaposi's sarcoma (KS; OMIM 148000), which is composed of vessels and spindle-shaped cells, was first described by Kaposi in 1872 as 'idiopathic multiple pigment-sarcoma of the skin'.⁹⁸⁹ The epidemic type of KS, first reported in the United States in 1981, has provoked considerable interest in this previously uncommon condition.⁹⁹⁰⁻⁹⁹² More than 10,000 articles are currently referenced on the Medline database.⁹⁹³ There are four clinicopathological types: classic, African (endemic) type, a variant associated with immunosuppressive therapy, and an HIV-associated (epidemic) type.⁹⁹⁴ HHV-8 is the etiological agent in all types.⁹⁹⁵

Classic type

The classic type affects predominantly men in the fifth to seventh decades. It is exceedingly rare in children⁹⁹⁶ and uncommon in adolescents.⁹⁹⁷ There is an increased incidence in Jews, eastern Europeans, and people of Mediterranean origin.⁹⁹⁸⁻¹⁰⁰⁰ It has also been reported in other races.¹⁰⁰¹⁻¹⁰⁰⁶ In most cases, the lesions are limited to the skin of the extremities, particularly the lower part of the legs and feet; occasionally, lymph nodes and other organs are involved. The penis is sometimes involved.¹⁰⁰⁷⁻¹⁰⁰⁹ The incidence of visceral involvement varies

in different areas of the world, possibly reflecting the incidence of the different serotypes of the HHV-8 virus.¹⁰¹⁰ Mild immune suppression and genetic factors may also contribute to the development of KS in some patients with the classic type of the disease.¹⁰¹¹⁻¹⁰¹⁵ Idiopathic CD4⁺ lymphocytopenia has been present in rare cases of KS.^{1016,1017} Lymphedema sometimes precedes or follows the appearance of the lesions.¹⁰¹⁸⁻¹⁰²⁰ It has also been associated with lipedema, a form of lipodystrophy.¹⁰²¹ The classic type of KS has a chronic course, with the development of more lesions; death is usually due to other causes. Immunosuppression and an older age are associated with a poorer outcome.¹⁰²² There is an increased risk of developing other tumors, particularly malignant lymphomas.¹⁰²³⁻¹⁰²⁸ Spontaneous regression of the lesions may occur.

Seropositivity to HHV-8 has been found in 40% of first-degree relatives of patients with classic KS.¹⁰²⁹ The specific relationship with the index person had no significant effect on the prevalence of seropositivity in the family members, suggesting a predominantly nonsexual horizontal transmission route of the virus.¹⁰²⁹

African (endemic) type

The African type of KS is endemic in areas of tropical Africa, with the highest prevalence in eastern Zaire and western Uganda.¹⁰³⁰ There are three main subtypes,¹⁰³¹ the most common being nodular disease, similar to classic Kaposi's sarcoma with a benign clinical course. A more aggressive subtype is characterized by extensive florid and infiltrative skin lesions, which may involve soft tissues and underlying bone.¹⁰³² This subtype may present with large, fungating tumors.¹⁰³³ A lymphadenopathic subtype occurs predominantly in children: in this variety, there is involvement of lymph nodes, often without cutaneous lesions, and the prognosis is poor.¹⁰³⁴ There is a marked male predominance in endemic African KS.¹⁰³⁵ Epstein-Barr virus (EBV), as well as HHV-8, is frequently present in African cases.^{1036,1037} HIV-related cases are now being seen in areas of Africa, including in women.^{1038,1039} In one study from Togo, HIV serology was positive in 78.5% of patients with KS.¹⁰⁴⁰ The mortality rate at 2 years was 45% for AIDS-associated KS and 5% for African KS (HIV-).¹⁰⁴⁰

Kaposi's sarcoma associated with immunosuppressive therapy

Kaposi's sarcoma is a rare complication of organ transplantation, chemotherapy for tumors, and long-term corticosteroid and other immunosuppressive treatment for a variety of dermatological and other conditions, including hepatitis C infection.^{1024,1041-1046} It has been reported following corticosteroid treatment of patients with bullous pemphigoid^{1047,1048} and pemphigus¹⁰⁴⁹⁻¹⁰⁵¹ and also in patients with lymphoma treated with interferon.¹⁰⁵² It has been seen in renal transplant recipients^{1053,1054} but only rarely in cardiac transplant recipients. In two studies, the prevalence in renal transplant patients was 0.3 and 1.6%, respectively.^{1055,1056} In cardiac transplant recipients, the prevalence has been reported as 0.41%.¹⁰⁵⁷ It may also follow bone marrow transplantation.¹⁰⁵⁸ The male preponderance of cases is less marked than in the other forms of the disease; younger age groups are also affected. Tumors may appear within a short time of commencement of immunosuppressive therapy and may regress spontaneously following cessation of therapy.¹⁰⁴² Progression of classic KS has been associated with the use of rituximab, a monoclonal antibody directed against the CD20 antigen of B cells.¹⁰⁵⁹ There may be a more aggressive clinical course than in classic KS. Death may follow widespread disease, particularly from gastrointestinal hemorrhage.

Epidemic (HIV-associated) type

The epidemic type of KS is associated with AIDS, caused predominantly by the retrovirus human immunodeficiency virus type-1 (HIV-1).¹⁰⁶⁰⁻¹⁰⁶² In West Africa, AIDS is also associated with a second retrovirus, HIV-2; KS is also reported in this group.¹⁰⁶³ In Europe, the United States, and Australia, this form of KS is most common in

homosexual and bisexual men. HIV-associated KS also occurs in women, children, hemophiliacs, and intravenous drug users. The prevalence of the tumor in risk groups other than homosexual and bisexual men varies. It is uncommon in hemophiliacs and in recipients of blood transfusions who develop HIV infection.^{1064,1065} There is an intermediate risk in intravenous drug users.¹⁰⁶⁶ In women who have contracted HIV infection by sexual contact, the prevalence of KS is highest in those who have had a bisexual partner.¹⁰⁶⁵ KS in HIV infection is rare before the age of 15 years.¹⁰⁶⁵ Children of parents in high-risk groups for KS and children who acquire HIV infection by blood transfusion have the highest risk of developing KS.¹⁰⁶⁷ The proportion of patients with AIDS who develop KS declined from 33% in 1981 to approximately 10% in 2000.¹⁰⁶⁸ It has declined further in Western countries with the more widespread use of highly active antiretroviral therapy (HAART),¹⁰⁶⁹ but because 99% of the 40 million patients with AIDS in the world cannot afford HAART, KS is still a very common problem.¹⁰⁷⁰ KS exhibits a less aggressive presentation in patients already receiving HAART.¹⁰⁷¹

The distribution of lesions in this form differs from that in classic KS. The trunk, arms, head, and neck are frequently involved. Lesions are usually multiple. Skin lesions in one case were localized to areas of tacrolimus application.¹⁰⁷² There is frequent involvement of mucosal surfaces and internal organs. The musculoskeletal system may also be involved.¹⁰³² In one autopsy study, the lungs were involved in 37% of cases, the gastrointestinal tract in 50%, and lymph nodes in 50%; 29% had evidence of visceral lesions without skin lesions.¹⁰⁷³ The extent of cutaneous involvement does not correlate well with the extent of visceral disease.¹⁰⁷⁴ The clinical course ranges from chronic to rapidly progressive. Most patients die from opportunistic infections or other complications of AIDS rather than from KS. In one large series of AIDS patients, survival was best in those whose only manifestation was KS.¹⁰⁷⁵ The lesions may regress spontaneously.¹⁰⁷⁶

Skin lesions are similar in all groups, but in the epidemic form they tend to occur earlier and to be smaller and more subtle. Early lesions are brown to red macules or patches that may resemble a bruise. Papules, nodules, and plaques may be bluish or purple in color and may ulcerate. Unusual presentations include occurrence in a lymphoedematous penis,¹⁰⁷⁷ a subtle penile lesion in the classic variant,¹⁰⁷⁸ zosteriform distribution,¹⁰⁷⁹ the Koebner phenomenon,^{1080,1081} and localization to an area of previous radiation.¹⁰⁸² Conjugal KS has been reported, but because the cases occurred in an HHV-8 endemic area (both were HIV[−]), it may have been a fortuitous occurrence.¹⁰⁸³

Etiology and pathogenesis

In 1994, Chang *et al.* identified DNA belonging to a novel virus in tissue affected by KS. This virus, HHV-8, was originally known as Kaposi's sarcoma-associated herpesvirus (KSHV).¹⁰⁸⁴ It has now been detected in all epidemiological forms of KS.^{1085–1091} The occasional negative case may be related to technical difficulties with the identification.¹⁰⁹² HHV-8 has also been implicated in the pathogenesis of multicentric Castleman's disease and primary effusion lymphomas.^{1093–1096} The virus is not ubiquitous in the community, and seropositivity is limited to a small percentage of the population.¹⁰⁹⁷ However, there are small geographical areas in Italy with a high incidence of the classic type of KS; they appear to be 'hot spots' for HHV-8 infection.¹⁰⁹⁸

The mode of transmission of the virus has attracted considerable attention. HHV-8 is not shed in appreciable amounts in seminal fluid or from the rectum.^{1098,1099} The virus is found in oral secretions.¹¹⁰⁰ Saliva containing significant amounts of HHV-8 could be the source of most infections in the general population.¹¹⁰⁰ It appears that penile-oral contact is a high-risk activity, but this is obviously not the entire 'story'.¹⁰⁹⁸ The virus was found in 44% of the heterosexual partners of patients with classic KS, but this study did not categorize the sexual contact/practices involved.^{1101,1102} A more recent study concluded that

a nonsexual horizontal transmission route of the virus seems likely in endemic cases.¹⁰²⁹ Transmission through needle sharing in drug use is another documented method of spread.¹¹⁰³

As with other cell-transforming DNA viruses, infection with HHV-8 alone is probably not sufficient for the development of KS; additional cofactors are probably required.^{999,1104} A good illustration of this is the absence of KS among Ethiopian immigrants to Israel despite high seroprevalence of HHV-8 (39.1%).¹¹⁰⁵ Isolated cases have been reported in which HHV-8 has been associated with other viruses, such as EBV¹¹⁰⁶ and HPV (in the case of penile lesions of KS).^{1107,1108} Furthermore, the explosive incidence of HIV-associated KS in the early 1980s (later in some countries) resulted from colliding epidemics of HIV and HHV-8 infections in the homosexual and bisexual communities.^{1198,1109} KS is said to be 20,000 times more common in patients with HIV infection/AIDS than in the general population.¹⁰⁶⁸ In most cases, no cofactors have been identified.¹¹¹⁰ Attention has focused on the role of iron as a cofactor. Some of the countries with a high prevalence of classic and endemic KS have areas with iron oxide-rich volcanic clays. Anecdotally, it has been reported on the palm in a metallurgist with regular contact with iron filings.¹¹¹¹ The p53 tumor suppressor gene is an inconsistent finding and appears not to have a significant role as a cofactor.^{1112–1115} Studies of HLA subtype in patients with HIV-associated and the classic form of the condition have suggested a significant association with HLA-A2, -B5, -B8, -B18, and -DR5.^{1055,1116,1117} Another study found a significant association of the classic subtype with DRB1*1104 and DQB1*0604.¹¹¹⁸ The CCR5-promoter mutation A59029G, which protects patients from HIV infection, does not protect against KS.¹¹¹⁹

HHV-8 infects CD19⁺ B cells as well as T cells, monocytes, endothelial-derived spindle cells,¹⁰⁹⁸ and CD34⁺ cells in the peripheral blood of patients with KS.¹¹²⁰ It induces the formation of IL-6, which stimulates the expression of VEGF, creating an angiogenic state.¹¹²¹ Overexpression of bcl-2 occurs in the majority of cases.¹¹²² Five subtypes of HHV-8 (A–E) have been recognized. The subtypes have specific geographic distributions.¹¹⁰⁰ Type C infection tends not to be associated with extracutaneous disease compared with subtypes A and B.⁹⁹⁵ Three classes of viral gene transcripts are present within the virus. They have different functions, one of which is viral replication.¹⁰⁰³

It has been considered that disseminated KS represents a multifocal reactive process rather than a true sarcoma with the potential to metastasize.^{1123–1125} In one study, the cell population was found to be polyclonal, but another has shown a monoclonal population in multifocal lesions.¹¹²⁶ The controversy can be partly resolved by regarding KS as binomial (hyperplastic/neoplastic), beginning as a reactive proliferation but behaving as a multifocal neoplasm in advanced stages.^{1018,1127–1130} Abnormalities have been detected in various angiogenic cytokines and cellular control systems.^{1127,1131–1136} One such example involves the matrix metalloproteinases (MMPs), a family of 23 endopeptidases capable of degrading extracellular matrix of connective tissue, thereby facilitating tumor invasion.¹¹³⁷ Some are involved in angiogenesis. Lesional cells in KS are immunoreactive for MMP-1, -2, -3, -7, -9, and -13 but not MMP-14.¹¹³⁷ This is the rationale for the clinical trials involving inhibitors of MMP (COL-3, a modified tetracycline) for the treatment of this disease.¹¹³⁷ Interestingly, several antiretroviral agents currently in use have been shown to induce KS regression by directly blocking angiogenesis because of their ability to inhibit the activation of MMP-2.¹¹³⁷ The spindle cells are thought to be the proliferating component, whereas the endothelial cell population is thought to undergo a reactive hyperplasia. Other evidence suggests that the spindle cell elements show endothelial differentiation.^{1138–1145} Whereas KS tissue shows an expression of endothelial markers, KS-derived cell cultures express mesenchymal, non-endothelial markers. This has led to much of the confusion relating to these cells.¹¹⁴⁶ Chronic stimulation of endothelial cells (possibly by viral infection) can produce

transdifferentiation to a spindle-shaped cell.¹¹⁴⁷ The peripheral blood of patients with KS contains circulating cells capable of *in vitro* differentiation toward KS-like spindle cells. Chemokines in tissues might lead to their targeted deposition and growth.¹¹⁴⁸ Derivation from lymphatic endothelium has also been suggested.¹¹⁴⁹ This is supported by the finding of podoplanin, a marker of lymphatic endothelium, in this tumor. It is detected by the antibody D2-40.^{8,1150–1152}

Treatment of Kaposi's sarcoma

The response of a disease to various treatments may provide a valuable insight into its etiology and pathogenesis. Treatment with IFN- α -2a has been associated with regression of the lesions, although HHV-8 DNA persists in lesional skin.^{1153,1154} However, with HAART there has not only been regression of the lesions but also undetectable levels of HHV-8 DNA.^{1155–1157} The advent of HAART has led to a declining incidence of KS.¹¹⁵⁸ Remission of lesions in renal transplant recipients may follow a reduction in the immunosuppressive therapy.⁹⁹⁵

The treatment goals for KS include (1) symptom palliation; (2) shrinkage of tumor to alleviate edema, organ compromise, and psychological stress; (3) the prevention of disease progression; and (4) perhaps cure.⁹⁹³ Antiretroviral therapy is the first-line treatment of AIDS-related KS.¹¹⁵⁹ For patients with widely disseminated,¹¹⁶⁰ symptomatic KS, anaplastic KS,¹¹⁶¹ or in elderly patients with significant disease and comorbidities, pegylated liposomal doxorubicin is the treatment of choice.⁹⁹³ Other treatments include paclitaxel,^{1162,1163} the MMP inhibitor COL-3 and 9-*cis*-retinoic acid (both associated with problematic side effects),^{993,1164} sirolimus in transplant patients to replace other immunosuppressive drugs (it has antiangiogenic properties),^{994,1051,1054,1165} radiotherapy,^{1032,1166} topical imiquimod 5% cream, IFN- α ,^{997,1167} and surgery. Imaging with ^{99m}Tc-MIBI can be used to give more precise staging of the disease. It can be used to assess response to treatment.³⁹⁷

Histopathology

The microscopic appearance of the lesions is identical in the different types of KS.^{1168,1169} They evolve through patch, plaque, and nodular stages.¹¹⁷⁰ The earliest lesions, corresponding to the flat macule or patch stage, are predominantly vascular in nature. Within the dermis, there is a proliferation of irregular, often jagged, vascular channels that partly surround pre-existing blood vessels in some areas. This characteristic appearance has been termed the 'promontory sign' (Fig. 38.39).⁸⁹⁸ The vascular proliferation is also present about appendages and between collagen bundles. The vessels are thin walled and lined by plump or inconspicuous endothelial cells. Scattered groups of perivascular lymphocytes and plasma cells may also be present (Fig. 38.40). Extravasated erythrocytes and deposits of hemosiderin are also found in the dermis.

The papules, nodules, and plaques consist of a dermal proliferation of interlacing bundles of spindle cells and intimately related, poorly defined slit-like vessels (Fig. 38.41). The proportion of vessels and spindle cells varies. There is an associated inflammatory cell infiltrate consisting predominantly of lymphocytes and plasma cells. Dilated thin-walled vessels are found at the periphery of the tumor. The spindle cell component shows variable nuclear pleomorphism. Mitotic figures are present but not usually frequent. Erythrocytes can be seen within vascular lumina and extravasated in and around the lesion.

Clusters of eosinophilic hyaline globules, varying in size from just visible with the light microscope to larger than an erythrocyte, may be seen within spindle cells and macrophages or in an extracellular location. These were first described in African cases, but they are also seen in classic KS and in the epidemic form.^{1123,1171} They resemble Russell bodies and are PAS positive, stain bright red with Mallory's trichrome stain (Fig. 38.42), and are autofluorescent.¹¹⁷² They are seen

Figure 38.39 Kaposi's sarcoma. Dilated irregular vascular channels surround a pre-existing vessel ('promontory sign'). (H&E)

Figure 38.40 Kaposi's sarcoma. Lymphocytes and plasma cells are present in the stroma adjacent to an irregularly shaped vascular channel. (H&E)

Figure 38.41 Kaposi's sarcoma. (A) This variant is composed of vascular spaces and spindle-shaped cells. (B) Parts of another lesion show atypical spindle cells and less obvious vessels. (H&E)

Figure 38.42 Kaposi's sarcoma. Small hyaline globules are present in the cytoplasm of some macrophages and spindle-shaped cells. (Mallory's trichrome $\times 1500$)

Figure 38.43 Lymphangioma-like area in a Kaposi's sarcoma. Deeper areas resembled the more usual tumor. (H&E)

in early patch lesions in some cases.¹¹²³ They appear to represent effete red blood cell fragments that have been phagocytosed.¹¹⁷³ Erythrophagocytosis by tumor cells has been described in all stages of Kaposi's sarcoma.¹¹⁷⁴ Apoptosis of endothelial cells is seen quite often in plaques and nodules; it is seen less often in patch-stage lesions.¹¹⁷⁵ Lesions regressing as a consequence of HAART become surrounded by a dense fibrous stroma that eventually obliterates the lesion.^{1158,1176} Pharmacologically induced regression is characterized by a complete loss or decrease in spindle cells, increased lymphocytes, and dermal siderophage deposition.¹¹⁷⁷

Lymphangioma-like KS is an uncommon variant accounting for less than 5% of all cases.^{1178–1180} It consists of grossly dilated channels lined by flattened endothelial cells with a bland appearance (**Fig. 38.43**).¹¹⁸¹ There are irregular, anastomosing channels, closely applied to the dermal collagen, with slender papillary projections into the lumen. Most of the spaces are devoid of erythrocytes, further enhancing the lymphangioma-like features. Clinically, the lesions may have a bulla-like appearance.¹¹⁸² There is usually an admixture of more typical lesions. There is strong reactivity of the tumor cells with anti-HHV-8 latent nuclear antigen-1 (LNA-1).¹¹⁸³

Pyogenic granuloma-like KS is a recently described variant of KS that closely simulates pyogenic granuloma.⁷²⁹ No distinguishing histological features are present. Only the presence of HHV-8 LNA-1 allows a distinction to be made.⁷²⁹

Intravascular KS is another histological variant.¹¹⁸⁴ It does not seem to be associated with a more aggressive behavior. The vascular channels have the morphological features of veins. There is an intravascular growth of interlacing fascicles of spindle cells with formation of cleft-like spaces, hyaline globules, and a lymphoplasmacytic infiltrate. The cells stain for HHV-8, CD31, and CD34.¹¹⁸⁴ The D2-40 marker was not used.

An *anaplastic form* has been reported in African and sporadic cases.^{1131,1185,1186} The anaplastic lesions exhibit greater cellularity, nuclear pleomorphism, and more frequent mitotic figures, and they may have areas resembling angiosarcoma or fibrosarcoma.^{1018,1185} In several cases, anaplastic KS developed in a lymphedematous (postmastectomy) arm, thus mimicking Stewart-Treves syndrome.^{1161,1187} Epidermal changes vary with the lesion and include atrophy and ulceration over raised lesions. A peripheral epidermal collarette is sometimes present about papules and nodules. Lesions with prominent hyperkeratosis sometimes occur.¹¹⁸⁸

Immunohistochemical studies have demonstrated the presence of CD31 and D2-40, the new marker for lymphatic endothelium in nearly every case tested.^{8,1150,1151,1189} CD34 and factor VIII-related antigen were noted in some of the earlier studies.^{1189,1190} HHV-8 can be detected by PCR in paraffin-embedded tissue, although the viral load appears to be low.^{1191,1192} It is much easier to perform immunohistochemistry using the commercially available antibody against HHV-8, LNA-1. It detects HHV-8 in the majority of cases.¹¹⁹³ It is largely confined to the spindle cells in the nodular phase, but it is found in the endothelial cells of the slit-like vessels in the early patch stage (Fig. 38.44).¹⁰⁰⁵ Calcitonin receptor-like receptor, which plays an important role in angiogenesis, is strongly expressed in KS and other vascular tumors.¹¹⁹⁴ Numbers of epidermal nerve fibers, as assessed by PGP 9.5 staining, are decreased in lesions of KS, and the reduction is more pronounced in HIV-associated KS than in Mediterranean KS or KS associated with immunosuppression.¹¹⁹⁵

The immunohistochemical demonstration of HHV-8 DNA may be a useful adjunct in the diagnosis of KS by fine needle aspiration¹¹⁹⁶ and also when difficult lesions are encountered.¹¹⁹⁷

Figure 38.44 Kaposi's sarcoma. Stromal spindle cells stain with antibody to HHV-8. (Immunoperoxidase stain for HHV-8)

Differential diagnosis

The early vascular lesions are subtle and must be differentiated from telangiectases, pigmented purpuric dermatosis, acroangiodermatitis, and low-grade angiosarcoma. The vessels in KS are usually more irregular than those in most developmental or acquired telangiectases, pigmented purpuric dermatosis, or acroangiodermatitis.⁸⁹⁹ An inflammatory infiltrate that includes plasma cells is found in some early lesions of KS. Pyogenic granuloma has now entered the list of differential diagnoses with the report of a pyogenic granuloma-like variant of KS (discussed previously). In low-grade angiosarcoma, there is usually some evidence of cellular atypia. Small intravascular endothelial buds are sometimes seen. Irregular jagged vessels, dissection of collagen bundles by vascular structures, and an inflammatory cell infiltrate may all be seen in low-grade angiosarcoma. The commercial availability of anti-HHV-8 test kits has removed much of the difficulty associated with the diagnosis of patch-stage lesions. A case combining features of KS and diffuse dermal angioendotheliomatosis was described prior to the availability of this test. Its exact nature is therefore speculative.¹¹⁹⁸

Lesions with a spindle cell component must be differentiated from cutaneous smooth muscle tumors, some forms of dermatofibroma (fibrous histiocytoma),¹¹⁹⁹ and spindle cell hemangioendothelioma.⁵⁴⁹ Smooth muscle tumors lack the intimate mingling of spindle cells, slit-like vessels, and eosinophilic globules, and they are usually positive for desmin intermediate filaments on immunoperoxidase staining. Aneurysmal fibrous histiocytoma can usually be differentiated from Kaposi's sarcoma because of the presence of foamy macrophages, multinucleate giant cells, and the overlying epidermal changes, which range from epidermal hyperplasia to basal budding resembling hair differentiation.

The lesions of spindle cell hemangioendothelioma closely mimic Kaposi's sarcoma, but the component vessels are usually more cavernous, and focally, the endothelial cells are epithelioid and vacuolated. Eosinophilic globules have not been reported in these tumors.

HEMANGIOPERICYTOMA

Hemangiopericytoma is a tumor first delineated by Stout and Murray in 1942.¹²⁰⁰ Enzinger and Smith have divided this uncommon tumor into two groups.¹²⁰¹ The usual form of hemangiopericytoma (adult type) occurs in adults and rarely in children. It arises in deep soft tissues, particularly the lower extremities, pelvis and retroperitoneum, and occasionally other organs.^{1201–1203} It rarely arises in the subcutis.^{1201,1202,1204} A second form (congenital or infantile hemangiopericytoma) is present at birth or arises in the first year of life; it is more common in boys.^{1205–1207} The tumors in this group are multilobulate and arise almost exclusively in the subcutis of the head and neck, extremities, or trunk; occasionally, they arise in the dermis.^{1201,1208} Most are solitary, but multiple lesions also occur.^{1205,1209} Conventional hemangiopericytomas have an unpredictable course and may recur after treatment; they may metastasize, predominantly to the lungs and bone.¹²⁰¹ Fewer than 25% of cases behave as malignant tumors.¹²¹⁰ Congenital and infantile tumors have a benign clinical course, although they may grow rapidly during infancy or be complicated by hemorrhage.^{1201,1211–1213} Hemangiopericytoma in children older than 1 year does not differ in behavior from the adult type.¹²¹⁴

Acquired ichthyosis has been reported in a patient with osseous hemangiopericytoma who had multiple liver metastases.¹²¹⁵

The concept of hemangiopericytoma has been questioned.¹²¹⁰ Many soft tissue sarcomas may have a 'hemangiopericytoma-like pattern'.¹²¹⁶ For example, the distinction between hemangiopericytoma and solitary fibrous tumor has become blurred.¹²¹⁷ Fletcher questions the existence of this entity because tumor cells have only a limited morphological similarity to pericytes. Furthermore, a diagnosis is made without

Figure 38.45 Hemangiopericytoma. This lesion, originally diagnosed as hemangiopericytoma, displays tightly packed cells and ramifying, 'staghorn-shaped' vessels. (H&E)

positive criteria.¹²¹⁰ Nappi *et al.* concluded that 'hemangiopericytoma represents both a pattern and a pathological entity ... and should be considered to represent an exclusionary interpretation'.¹²¹⁸ Infantile hemangiopericytoma is now considered by most authorities to be the same entity as infantile myofibromatosis, or one end of a spectrum of infantile myofibroblastic lesions.^{1210,1219,1220}

Histopathology¹²⁰¹

The *adult type* exhibits the characteristic pattern of tightly packed cellular areas surrounding endothelium-lined ramifying vessels (Fig. 38.45). The cell boundaries are poorly defined; the nuclei are round or oval. Tumor cells are separated from the endothelial cells by a basement membrane and are themselves surrounded by a meshwork of reticulin fibers. Histological variations include myxoid areas, fibrotic areas, and, rarely, osseous and cartilaginous metaplasia.¹²⁰¹ The deep variant with mature fat reported as a lipomatous hemangiopericytoma¹²²¹ has been regarded by others as a fat-containing variant of solitary fibrous tumor.¹²²² Epithelioid histiocytomas may exhibit hemangiopericytoma-like areas.^{1223,1224} Tumor cells express vimentin only; they are negative for α -smooth muscle actin and α -sarcomeric actin.⁸⁰⁸ Normal vascular pericytes are uniformly reactive for vimentin and α -isoforms of actin, and they sometimes stain for desmin and HLA-DR. Tumor cells also stain for factor XIIIa, CD34, CD57, and HLA-DR,¹²²⁵ but these are not specific markers. Pericytes express 3G5 ganglioside.¹²²⁶ Further studies are needed to determine if this marker leads to the retention of hemangiopericytoma as a diagnostic entity. Several studies have stressed the difficulty in predicting the behavior of these tumors from their histological appearance, but frequent mitotic figures, necrosis, hemorrhage, and increased cellularity are features that indicate a poor prognosis.¹²⁰² DNA flow cytometry and immunohistochemical stains for PCNA are not helpful in predicting outcome in these tumors.¹²²⁷

In one study, increased tumor expression of MGMT protein (O-6-methylguanine-DNA methyltransferase, a DNA repair enzyme) in meningeal hemangiopericytoma was found to correlate with decreased survival.¹²²⁸

Congenital and infantile hemangiopericytomas have the typical pattern of cells and vessels as described previously, but they are multilobulate, with perivascular and intravascular tumor outside the main

tumor mass.^{1201,1209} Endothelial proliferation within vascular lumina has been described.¹²⁰¹ Mitotic figures and necrosis may be seen but do not indicate a poor prognosis because these tumors have a benign course.¹²⁰⁵ Hemangiopericytoma-like areas are sometimes seen in infantile myofibromatosis (see p. 983), which affects infants and children and may involve skin and subcutis.¹²²⁹ Conversely, foci of cells having a spindled, myoid appearance typical of myofibroblasts can be seen in typical cases of infantile hemangiopericytoma. These cases show focal staining for actin. In another case, smooth muscle actin stained numerous cells around the vascular spaces and also some endothelial cells.¹²²⁰ This is similar to infantile myofibromatosis.¹²²⁰

Electron microscopy

Ultrastructural studies of adult cases have shown that the tumor cells are partially or completely surrounded by well-formed basement membranes. Pinocytotic vesicles and cytoplasmic filaments, sometimes with dense-body formation, are seen within the cells.¹²³⁰ More than half the cases do not show pericytic features.¹²³¹

KAPOSIFORM HEMANGIOENDOTHELIOMA

Kaposiform hemangioendothelioma is a locally aggressive vascular proliferation in infants and young children that usually presents in the skin as a single lesion, although a multifocal congenital case has been reported.¹²³²⁻¹²³⁴ Adult cases also occur.¹²³⁵ Requena and Ackerman suggested that it should be renamed kaposiform hemangioma because there are no reports of unequivocal metastasis.⁵⁵⁷ Weiss and colleagues, on the basis of their study of 33 cases in which 2 cases had regional lymph node involvement at the time of the primary excision, concluded that it should continue to be classified as a vascular tumor of intermediate malignancy. No distant metastases occurred.¹²³⁶

A variety of sites can be involved, including deep soft tissues of the upper extremities, thigh, chest wall, scalp, neck, and retroperitoneum.^{1236,1237} Earlier reports emphasized peritoneal and retroperitoneal sites.^{1238,1239} It is often associated with Kasabach-Merritt syndrome (OMIM 141000) or lymphangiomatosis.^{371,1232} Cases without the Kasabach-Merritt phenomenon are usually less than 8 cm in diameter, suggesting that tumors that grow no larger than this size are less likely to trap platelets in sufficient quantity to cause thrombocytopenia.¹²⁴⁰ If present, the Kasabach-Merritt syndrome can be treated with a stepwise regimen of prednisolone, dipyridamole, and interferon.¹²⁴¹ The outcome depends on the site and the extent of the disease. Deaths have been reported from the associated Kasabach-Merritt syndrome and lymphangiomatosis.¹²³⁶

Histopathology¹²³⁷

As with KS, there are interconnecting sheets or nodules of spindled endothelial cells lining slit-like or crescent-shaped vessels. The spindle cell fascicles are generally shorter and narrower than those found in KS.⁵⁶³ Small rounded vessels may also be seen. Unlike KS, there may be nests of epithelioid-like endothelial cells with eosinophilic cytoplasm containing hemosiderin and cytoplasmic vacuoles. Cellular atypia is minimal, and mitoses are infrequent. Hemosiderin may also be present in the spindle cells. Hyaline eosinophilic globules similar to those in KS are also seen. An occasional finding is microthrombi in vessel lumina. In the skin and subcutis, there is surrounding dense hyaline fibrosis. Spindle cells stain for CD34 and focally for CD31.^{1237,1242} In the series of 33 cases reported by Sharon Weiss and colleagues, the endothelial cells in the nodules expressed CD31, CD34, and FLI1 but not GLUT-1, LeY, or HHV-8.¹²⁴² In a series from Japan, all 4 cases expressed D2-40.⁷⁷⁸ In 3 cases, the response was markedly reactive, and in the fourth it was reactive in the peripheral area of KS-like proliferative capillaries and negative in the surrounding dilated vessels.⁷⁷⁸ In contrast, the staining was reversed in tufted angioma with

partial positivity in the dilated vessels but no staining in the cannonball-like proliferative capillaries.⁷⁷⁸ The tumor has some similarities to spindle cell hemangioma, but the latter occurs predominantly in adults, is superficial, and may have cavernous vessels and phleboliths. KS is usually multifocal; it is very rare in children, except as the endemic form.

In contrast to true KS, which is the principal differential diagnostic consideration, there is no molecular evidence of infection with HHV-8 in kaposiform hemangioendothelioma.¹²⁴³ However, Folpe and associates showed that kaposiform hemangioendothelioma does share potential immunoreactivity for VEGFR-3 with KS.¹²⁴⁴ Dabska tumor and some angiosarcomas also may express this marker.

ENDOVASCULAR PAPILLARY ANGIOENDOTHELIOMA OF CHILDHOOD

Endovascular papillary angioendothelioma of childhood has had a confusing taxonomic evolution. In the first report of this very rare vascular tumor, Dabska described it as malignant endovascular papillary angioendothelioma because it was locally invasive and appeared to have the potential to metastasize.¹²⁴⁵ Subsequently, others suggested that this lesion should be classified as of borderline malignancy because of its good long-term prognosis, minimal cellular atypia, and controversial metastatic potential.^{1246,1247} It was next regarded as a low-grade angiosarcoma,^{1248,1249} and on the basis of its staining pattern, it has been renamed **papillary intralymphatic angioendothelioma (PILA)**,⁹ reflecting its presumed lymphatic origin.

The majority of reported cases have been in children; rarely, adults are affected.¹²⁵⁰ There is a report of this lesion developing in a pre-existing vascular malformation in an adult.¹²⁵⁰ A recent case arose in a lymphangioma circumscriptum – further evidence of a lymphatic origin for the Dabska tumor.¹²⁵¹ A tumor showing some similarities to this entity has also been reported in a background of lymphedema.¹²⁵² In the majority of cases, the lesions are present at birth. They occur in a variety of sites, either as a diffuse swelling of the skin or as an intradermal tumor. The tumors enlarge and may eventually invade deeper soft tissues and bone. Metastasis to regional lymph nodes and lungs has been reported.¹²⁴⁵ One of the original patients reported by Dabska subsequently died of widespread pulmonary metastases, but it may have been a retiform hemangioendothelioma.¹²⁴⁹

Angiosarcoma has been reported to arise within an endovascular papillary angioendothelioma.¹²⁵³ However, most recent cases have been benign. This lesion may need re-evaluation once larger series have been published.³⁸⁷ For this reason, this tumor is now discussed with tumors that have ‘a variable behavior and outcome’.

Histopathology

There is some variability.^{1245,1254} Irregular vascular channels are present in the dermis and subcutis. They are lined by endothelial cells ranging from flattened to columnar in shape. Some cells have a ‘hobnail’ appearance. Within the lumina of these vessels are papillary structures covered by similar cells. The cores of the papillae are avascular and consist of fibrous tissue or peculiar eosinophilic hyaline globules, some with central clearing (Fig. 38.46). These features are not seen in retiform hemangioendothelioma.

Some of these vascular structures have a glomeruloid appearance. Lymphocytes are seen both within the lumina of the vascular channels, in intimate association with the endothelial cells, and in the extravascular stroma. There is nuclear hyperchromatism, and mitotic figures are present.¹²⁴⁵

Immunohistochemical and ultrastructural studies have confirmed the endothelial nature of the tumor cells and identified the hyaline globules as basal lamina-like material.^{1246,1247} Tumor cells are positive for

Figure 38.46 Endovascular papillary angioendothelioma (Dabska tumor). Within irregular vascular channels, there are papillary structures lined by hobnail endothelial cells and possessing avascular cores. (H&E)

vimentin, factor VIII-related antigen, CD31, and focally for CD34. They are negative for keratins, EMA, S100 protein, and desmin.⁹ VEGFR-3, a marker for lymphatic endothelia, was positive in all cases studied. The lymphatic endothelial marker D2-40 was positive in all three cases of Dabska tumor studied in one report,¹¹⁵¹ confirming the lymphatic nature of this tumor.

Fine needle aspiration cytology has shown small clusters of tumor cells in rosette-like arrangements and also papillary fragments with fibrovascular cores and hobnail-like cellular arrangements.¹²⁵⁵

MALIGNANT TUMORS

Several of the rare vascular tumors previously categorized as being of variable or uncertain behavior have been reclassified as malignant tumors, although it is acknowledged that they are usually associated with an excellent prognosis. The following tumors are considered in this category:

- Angiosarcoma and lymphangiosarcoma
- Epithelioid hemangioendothelioma
- Retiform hemangioendothelioma
- Composite hemangioendothelioma
- Malignant and atypical glomus tumors.

A review of cutaneous vascular tumors, including malignant lesions, was published in 2008 by Goh and Calonje.³⁸⁷

ANGIOSARCOMA AND LYMPHANGIOSARCOMA

The distinction between malignant tumors showing blood vessel differentiation (angiosarcoma) and those showing lymphatic differentiation (lymphangiosarcoma) has often been unclear in the past. The advent of the marker D2-40 has allowed a more reliable distinction to be made. Because it has been found that a subgroup of cases of apparent angiosarcoma, including the postirradiation cases of the breast, express D2-40, it is proposed to discuss these tumors together, but a brief discussion of lymphangiosarcoma is provided at the end of this section.

Approximately 60% of all angiosarcomas occur in the skin or soft tissue, with 50% of cutaneous cases occurring on the head and neck,¹²⁵⁶

although this was the site in 96% of cases in one series.¹²⁵⁷ It has a male-to-female ratio of 2.5:1.

There are three main clinicopathological subtypes: idiopathic cutaneous angiosarcoma of the head and neck, angiosarcoma complicating lymphedema, and postirradiation angiosarcoma.¹¹²⁴ A miscellaneous category is sometimes added.

Idiopathic cutaneous angiosarcoma of the head and neck^{1258–1261}

Idiopathic cutaneous angiosarcoma of the head and neck most commonly involves the upper part of the face or the scalp of elderly people.¹²⁶² Periorbital or eyelid involvement is sometimes seen.^{1263,1264} Men are affected more frequently than women.¹²⁶⁵ The lesions are single or multifocal, bluish or violaceous nodules, plaques or flat infiltrating areas; they may occasionally bleed or ulcerate. In one series, they measured 1–9 cm in diameter, but much larger cases are recorded.¹²⁵⁷ Rare clinical presentations include recurrent angioedema of the face,¹²⁶⁶ alopecia,¹²⁶⁷ an inflammatory process,¹²⁶⁸ a rosacea-like eruption,¹²⁶⁹ a rhinophyma-like lesion,¹²⁷⁰ and involvement of an area of radiodermatitis.¹²⁷¹ A clue to the presence of a head and neck angiosarcoma may be the presence of a positive head-tilt maneuver.¹²⁷² This simple test involves placing the head at a level below the heart. If a vascular tumor is present, the area of involvement becomes markedly more violaceous and engorged.¹²⁷²

Thrombocytopenia may develop as a consequence of enlargement of the primary lesion or the development of metastatic deposits.¹²⁷³ Extensive local growth is common, and margins are difficult to define surgically. Metastasis to regional lymph nodes and to the lungs occurs, often after repeated surgical excision of the primary growth. A reduction in adhesion molecules, such as cadherin, has been implicated in the local invasiveness and metastasis of angiosarcoma.¹²⁷⁴ The prognosis is poor. In one series, only 15% of patients survived for 5 years or more after diagnosis.¹²⁶⁵ It was 34% in a more recent series.¹²⁵⁷ This may reflect the fact that clinical diagnosis is often delayed until the lesions are advanced. Prolonged survival was recorded in three cases on the nose, but their diagnosis was made early, which may have contributed to the better survival.¹²⁷⁵ Complete spontaneous regression of the tumor has been reported.^{1276,1277}

Lymphangiosarcoma arising in chronic lymphedematous limbs

Since 1948, when Stewart and Treves recognized the syndrome of postmastectomy lymphangiosarcoma, the association of such tumors with chronic lymphedema has become well-known.¹²⁷⁸ In their original series, they described the appearance of purplish-red raised macular or polypoid tumors in the chronically edematous arm of women who had undergone radical mastectomy on that side. The tumors appeared on average 12.5 years after surgery. Similar tumors have been reported in men after mastectomy. They have also occurred in cases without lymph node dissection and without preceding edema. Much less commonly, similar tumors arise in the limbs of patients with chronic lymphedema due to other causes,¹²⁷⁹ including congenital lymphedema (Milroy's disease), lymphedema following other types of surgery, and chronic venous stasis.^{1280–1286} Lymphedematous tissue is immunologically vulnerable for the development of infections and neoplasms.¹²⁸⁷ Lymphangiosarcoma has also been reported in association with chronic filarial lymphedema, but it appears to be a rare complication of this condition.¹²⁸⁸ Rarely, cutaneous angiosarcoma has been reported in lymphedematous extremities that have developed as a complication of malignancies other than breast carcinoma, such as Hodgkin's disease.^{1289,1290} An angiosarcoma has also developed in a lymphedematous abdominal pannus.¹²⁹¹

Postirradiation angiosarcoma

Postirradiation angiosarcomas are rare and have been documented after radiotherapy for a variety of benign and malignant conditions.^{1292,1293} At least 10 cases of angiosarcoma have been reported

following irradiation of benign hemangiomas; the median latent period from irradiation to diagnosis of angiosarcoma was 21.8 years.^{1294,1295} Angiosarcomas have also been reported following treatment of eczema,¹²⁹⁶ tinea capitis, and sinusitis.¹²⁹⁷ This form of angiosarcoma is more common following therapy of a variety of malignant tumors,¹²⁹⁴ including carcinoma of the breast^{1298,1299} and cervix.¹³⁰⁰ With the advent of breast-conserving surgery and radiation as a common method of treating breast cancer, a type of angiosarcoma is seen that differs from the angiosarcoma arising in Stewart–Treves syndrome by its localization to the breast, its lack of lymphedema, and its shorter latency period.^{1301,1302} This new variant is multifocal at presentation in nearly half of the cases.¹³⁰¹ Multiple capillary lobules are a deceptively benign presentation of these postirradiation angiosarcomas of the breast.^{1303,1304} Angiosarcomas seem to form a morphological spectrum with the radiation-associated lesions described by Brenn and Fletcher in 2005 as AVLs.⁹⁸² AVLs comprise cases that were included in the past as acquired progressive lymphangioma and BLAP.⁹⁸² Although the benign-appearing lesions have behaved in a benign manner, one case progressed to angiosarcoma. Both the AVLs and the angiosarcomas arising in this setting stained with D2-40, but the number of cases tested was small.⁹⁸² So too do the lesions reported as BLAP. The latent period between treatment and diagnosis is reported to be shorter than that for benign conditions – an average of 12 years in one report¹²⁹² – but it may be much shorter.^{1298,1299} As noted previously in the discussion of atypical vascular lesions, the findings of Guo *et al.*⁹⁸⁴ and Mentzel and colleagues⁹⁸⁶ have expanded our knowledge of these lesions through the discovery that the regulator gene *MYC* is consistently amplified in secondary (postirradiation) angiosarcomas but not in atypical vascular lesions or in other radiation-induced sarcomas. This can be assessed both by molecular methods and through immunohistochemical staining for *MYC* in tissue sections.

Miscellaneous angiosarcoma

Angiosarcomas have been reported to arise in pre-existing benign vascular tumors,¹³⁰⁵ including lymphangioma,¹⁸⁹ and 'port wine' stains,¹³⁰⁶ and also in benign and malignant peripheral nerve sheath tumors.¹³⁰⁷ An epithelial variant has arisen in a deep-seated plexiform schwannoma.¹³⁰⁸ They have also occurred as a complication of varicose ulceration;¹³⁰⁹ trauma;¹³¹⁰ arteriovenous fistulae;¹³¹¹ renal transplantation;^{1312,1313} hereditary epidermolysis bullosa;¹³¹⁴ xeroderma pigmentosum;¹³¹⁵ a gouty tophus;¹³¹⁶ retained foreign materials such as shrapnel and surgical sponges; and adjacent to a Dacron® vascular prosthesis.¹³¹⁷ Angiosarcoma of the scrotum has arisen after radiation therapy for cancer of the rectum.¹³¹⁸ HHV-8 has been detected in several cases, but it has been specifically excluded in others.^{1311,1319,1320} It has been detected in the lesions of two patients with AIDS who developed angiosarcoma.¹³²¹ Intravascular dissemination of an angiosarcoma, mimicking angioendotheliomatosis, has been described.¹³²² These two conditions have been noted to arise in association with each other.¹³²³ A case that produced granulocyte colony-stimulating factor has been reported.¹³²⁴

In 2008, Sharon Weiss and colleagues reviewed 69 cases of sporadic cutaneous angiosarcoma.¹³²⁵ Because the group included not only head and neck tumors (49 of the group) but also tumors at other sites, this discussion has been placed at the end of the recognized subtypes. Tumors associated with radiation or lymphedema were excluded. Recurrences developed in 18 patients (26%) and metastasis in 15 (22%). Thirty patients died of the disease. Older age, anatomic site (trunk and extremities cases did worse than head and neck cases), necrosis, and epithelioid features correlated with increased mortality.¹³²⁵ These features seemed to diminish in importance with increased tumor size.

Various treatments have been used for angiosarcoma with limited success. These include surgery, paclitaxel (a taxane with antiangiogenic

and apoptotic effects),^{1326,1327} docetaxel,¹³²⁸ liposomal doxorubicin,¹³²⁹ liposomal doxorubicin and radiotherapy,¹³³⁰ liposomal doxorubicin and intralesional pegylated IFN- α ,¹³³¹ combination IFN- α -2a and 13-*cis*-retinoic acid,¹³³² IFN- α -2b with IL-2 and surface radiotherapy,¹³³³ arterial IL-2,^{1334,1335} and combined chemotherapy and radiotherapy in various schedules.¹³³⁶ Surgery is the preferred treatment for lesions on the scalp, but obtaining negative margins can be difficult.¹³³⁷ Postoperative radiation is recommended for tumors at this site.¹³³⁷

Histopathology

The appearances are similar in the three groups.^{1258–1260,1278} The lesions are poorly circumscribed dermal tumors that infiltrate subcutaneous fat and other tissues and often have a multifocal distribution. Angiomatous and solid patterns may be seen (Fig. 38.47). In the angiomatous areas, a meshwork of anastomosing dilated vessels extends between pre-existing dermal collagen bundles and around skin appendages. The vessels are irregular and lined by crowded endothelial cells, which range in appearance from virtually normal-looking to plump atypical protuberant cells with enlarged hyperchromatic nuclei (Fig. 38.48). Papillary processes may extend into the lumen of the vessel. In the solid areas of the poorly differentiated tumors, the cells vary from spindle-shaped to polygonal. A spindle cell pattern may predominate.¹³³⁵ Some areas may resemble KS.¹³³⁸ Cytoplasmic vacuoles resembling primitive vascular lumina may be seen in some cells. Reticulin stains show that the cellular proliferation is on the luminal side of the reticulin fibers in the angiomatous areas. Generally, as architectural differentiation decreases, cytological atypia and cell size tend to increase.¹²⁵⁹ Lymphocytic infiltrates are commonly seen and may obscure the underlying lesion, particularly in well-differentiated tumors with minimal cellular atypia.¹²⁵⁹ Mast cells appear to be increased.^{1315,1339} Distinguishing the well-differentiated angiomatous areas from benign vascular proliferations depends on the recognition of cellular atypia, the presence of crowding of lining cells and of solid papillary clusters of cells, and an irregular interconnecting pattern of vessels. The use of antibodies specific for signal transduction pathways is a feasible method for distinguishing benign from malignant endothelial processes in paraffin-embedded tissue. There is strong expression of mitogen-activated protein kinase (MAPK) in benign endothelial tumors and a greatly decreased expression in angiosarcoma.¹³⁴⁰ Infectious endothelial lesions (KS and verruga peruana) stain strongly.¹³⁴⁰ Caveolin, a scaffolding cell membrane protein, has a higher level of expression in benign vascular tumor than in angiosarcomas, including the well-differentiated variants.¹³⁴¹ It has been suggested that caveolin expression might be useful in separating benign and malignant vascular tumors.¹³⁴¹ The differentiation of early lesions from early lesions of Kaposi's sarcoma may be dependent on clinicopathological correlation.

Many immunohistochemical markers for endothelial cell differentiation have been used, including factor VIII-related antigen, *Ulex europaeus*-1 lectin,^{656,1342} PAL-E,¹³⁴³ CD34,¹²⁵⁸ and CD31.¹¹⁹⁰ Epithelioid angiosarcomas often express CK8 and CK18 (~50%), whereas the nonepithelioid types express cytokeratin (CK) 7, CK8, and CK18 in approximately 20% of cases. EMA is expressed in approximately one-third of nonepithelioid angiosarcomas,¹³⁴⁴ although the figure was lower than this in a recent study.¹³⁴⁵ Thus, caution is needed in interpreting EMA positivity as evidence for an epithelial tumor. The monoclonal antibody AE1, which does not react with CK7, -8, and -18, is advantageous in the differential diagnosis of angiosarcoma and carcinoma.^{1344,1346} Angiosarcomas also express WT1.⁴⁶⁷ A variety of vascular tumors, including angiosarcoma, express annexin II, also known as p36.¹³⁴⁷

Poorly differentiated tumors are, unfortunately, less likely to stain with immunohistochemical markers than are well-differentiated tumors, in which the vascular differentiation is already more obvious.

Figure 38.47 (A) Angiosarcoma. (B) The vascular channels are lined by atypical endothelial cells. (H&E)

Figure 38.48 (A) Angiosarcoma. Telangiectatic spaces are present. (H&E) (B) The endothelial cells stain for CD31. (Immunoperoxidase stain)

In some cases, the use of frozen instead of paraffin sections and also special fixation techniques may produce positive reactions. Currently, CD31 appears to be the most useful marker for endothelial differentiation, being both relatively sensitive and specific compared to other markers.^{1190,1348} *Ulex europaeus*-1 lectin labels some nonvascular neoplasms, as does CD34.¹¹⁹⁰ Factor VIII-related antigen was positive in only 29% of non- or poorly vasoformative areas of angiosarcoma in one study.¹³⁴⁸ CD31, CD34, and *Ulex europaeus*-1 lectin label blood vessels as well as lymphatic endothelium.¹¹⁹⁰ The presence of factor VIII-related antigen in the endothelium of blood vessels and its absence in that of lymphatics has been reported by some¹³⁴⁹ but not by others.¹³⁵⁰ PAL-E monoclonal antibody is reported to be more specific for blood vessel endothelium.¹³⁴³ Further studies are needed to confirm the specificity of VEGFR-3 for lymphatic endothelium. Initial studies appear promising.⁹ D2-40 is the latest marker of lymphatic endothelium to appear.

Ultrastructural and immunohistochemical studies have confirmed that postmastectomy lymphangiosarcomas are of endothelial origin^{1349,1351,1352} and not secondary breast carcinoma as has been sug-

gested.¹³⁵³ As alluded to in the introduction, the distinction between angiosarcoma and lymphangiosarcoma has, in some cases, become blurred with the use of modern investigative techniques. Immunohistochemical studies have suggested that tumors arising in edematous extremities are angiosarcomas rather than lymphangiosarcomas.^{1349,1354} One study of angiosarcoma of the face and scalp suggested that these tumors are more akin to lymphangiosarcomas than angiosarcomas.¹³⁵⁵ As noted previously, poorly differentiated tumors tend to lose the characteristic cell markers that would indicate their nature.

Electron microscopy

Ultrastructural features of blood vessel endothelium include well-formed junctional complexes of the zonula adherens type, a well-developed basal lamina, and Weibel-Palade bodies.¹³⁵⁶ Lymphatic endothelial cells are said to lack Weibel-Palade bodies; to have cell junctions that are inconspicuous; and to have incomplete, if any, basal laminae.

Lymphangiosarcoma

It has already been stated that there is a subset of angiosarcomas that stain with lymphatic markers and are presumably lymphangiosarcomas. Cases are now starting to appear in the literature that are being reported as lymphangiosarcoma on the basis of D2-40 staining of the cells. Lymphangiosarcomas arising on the head and neck have similar clinical features as angiosarcomas at that site, although lymphedema was mentioned as being present in one report.¹³⁵⁷

Differential diagnosis

Poorly differentiated tumors with polygonal and epithelioid cells can resemble carcinomas and even amelanotic melanoma.¹³⁵⁸ Immunohistochemical markers for keratins and S100 protein will help to distinguish between these tumors, although S100⁺ angiosarcomas have been reported.^{1358,1359} *Epithelioid, spindle, and granular cell* variants of angiosarcoma have also been described.⁵⁶³ The epithelioid variant sometimes expresses keratin.^{1279,1344,1360,1361} When it occurs on the breast, the epithelioid angiosarcoma may be mistaken for mammary carcinoma, although the latter tumor does not express CD34 and CD31. In epithelioid angiosarcoma, up to one-third of the neoplastic cells can express MIB-1.¹³⁶² Another histological variant is the *verrucous angiosarcoma*, in which there are striking verrucous changes in the overlying epidermis.¹³⁶³ Another variant, which may be mistaken for cutaneous lymphoma, is the *pseudolymphomatous* variant.¹³⁶⁴ It consists of irregular anastomosing vascular channels with pleomorphic endothelial cells that express CD31, CD34, and D2-40. There is a dense lymphocytic infiltrate between the vessels obliterating and destroying some of the channels. Germinal centers may also be present.¹³⁶⁴

The pseudoangiomatous variant of atypical fibroxanthoma can closely resemble angiosarcoma, especially when some of the constituent cells express CD31 or FLI-1.¹³⁶⁵ In this scenario, it is helpful to note the staining pattern of CD31, which may be granular and cytoplasmic rather than strong and membranous, or to perform other stains such as ERG, an ets family transcription factor that appears to be highly specific for malignant vascular tumors but is negative in atypical fibroxanthoma.¹³⁶⁵ In addition to the above-mentioned pseudolymphomatous angiosarcoma, lymphoma can be mimicked by the CD30⁺ variant of epithelioid angiosarcoma,¹³⁶⁶ recently reported in a radiation-induced angiosarcoma that was initially misdiagnosed as T cell lymphoma.^{1367,1368} A signet-ring cell angiosarcoma has been reported, which has resemblances to other signet-ring cell tumors, particularly signet-ring cell carcinomas of the gastrointestinal tract.¹³⁶⁹ Foamy cell angiosarcoma can have a misleadingly bland microscopic appearance and an obvious resemblance to xanthomatous or xanthogranulomatous

lesions.¹³⁷⁰ In all of these unusual variants of angiosarcoma, an index of suspicion is necessary, along with close inspection for irregular, anastomosing vascular channels and immunostaining with a battery of endothelial cell markers.

EPITHELIOID HEMANGIOENDOTHELIOMA

Epithelioid hemangioendothelioma is a rare vascular tumor of endothelial cell origin with a clinical course intermediate between hemangioma and angiosarcoma.¹³⁷¹ Although most cases occur in soft tissues and other organs, including bone and liver, these tumors have also been reported in the skin,¹³⁷²⁻¹³⁸⁰ usually on the extremities.¹³⁸¹ It may occur at all ages, including childhood.¹³⁸² Skin lesions have been reported with underlying bone lesions.¹³⁸³ Cutaneous lesions may have unusual clinical features with a delay in diagnosis.^{1384,1385} These tumors have low-grade malignant potential. They may represent a microsatellite stable tumor.¹³⁸¹ Metastasis of deep tumors has occurred, but cutaneous lesions that are resectable seem to do much better. Nevertheless, a metastasizing lesion of the nose has been reported in a child.¹³⁸⁶

A 1;3 translocation has been identified in two cases of this tumor.¹³⁸⁷ Its full characterization is t(1;3)(p36.3;q25).

Epithelioid hemangioendothelioma has been successfully treated with imiquimod 5% cream.¹³⁸⁸ Surgical excision is usually carried out, when feasible.

Histopathology

There is a proliferation of nests and cords of plump, epithelioid to spindle-shaped endothelial cells in a fibromyxoid stroma. Many of the cells contain cytoplasmic vacuoles. They may displace the nucleus and resemble signet-ring cells.¹³⁸⁴ Well-formed vascular channels are not a feature of this tumor.¹³⁷² Slight cellular pleomorphism and occasional mitotic figures are sometimes present (Fig. 38.49). A conspicuous spindle cell element may rarely be present.^{1389,1390} Such cases may represent a composite hemangioendothelioma (see later).¹³⁹⁰ Lamellar bone has been reported in one case.¹³⁹¹ These tumors may be difficult to distinguish from secondary adenocarcinoma, but the cells stain for *Ulex europaeus*-1 lectin, factor VIII-related antigen, CD31, and CD34. Cases are always positive for at least one vascular endothelial marker but not usually all.¹³⁸⁰ Approximately half the cases express smooth muscle actin.¹³⁷⁷ Occasional cases express cytokeratin.^{1371,1392} Using specific keratin markers, the cells of epithelioid hemangioendothelioma express K7 and K18 in the majority of cases.¹³⁴⁴ An epithelioid variant of angiosarcoma has also been described (discussed previously), but in this tumor there are largely confluent sheets of tumor cells with greater cellular atypia and areas of necrosis.^{1393,1394} They also need to be distinguished from an epithelioid angiomatous nodule (see p. 1090). This tumor tends to have well-formed blood vessels, each with a discernible lumen.¹³⁸⁴

Electron microscopy

Features include immature cell junctions, abundant intermediate filaments, Weibel-Palade bodies, and intracytoplasmic lumen formation; lumina may contain red blood cells.¹³⁷¹

Differential diagnosis

Two particular diagnostic problems are worth noting in the evaluation of epithelioid hemangioendothelioma. First, one might focus on the cord-like arrays of polygonal cells in some cases, leading to a misinterpretation of metastatic carcinoma. Second, one could label other lesions with extensive cytoplasmic vacuolization erroneously

Figure 38.49 Epithelioid hemangioendothelioma. (A) There are aggregates of epithelioid endothelial cells. Cytoplasmic vacuoles are apparent, with displacement of nuclei resembling signet-ring cells. There is mild nuclear pleomorphism. (B and C) Another example of epithelioid hemangioendothelioma, showing greater nuclear pleomorphism and mitotic activity. (H&E)

as adipocytic in nature. The application of electron microscopy or immunohistochemical studies for epithelial and endothelial determinants is useful in resolving these uncertainties. Epithelioid hemangioendothelioma regularly contains Weibel-Palade bodies ultrastructurally, and it is consistently immunoreactive for von Willebrand factor, CD31, CD34, FLI1, and thrombomodulin. As noted previously, a small proportion of cases of epithelioid hemangioendothelioma aberrantly express keratin proteins, particularly CK7 and CK18, making it desirable to also study other epithelial markers, such as epithelial membrane antigen, as well as more than one endothelial determinant if this tumor type is being considered in the differential diagnosis.

RETIFORM HEMANGIOENDOTHELIOMA

In 1994, Calonje *et al.* described 15 cases of retiform hemangioendothelioma, which they regarded as a low-grade angiosarcoma.¹³⁹⁴ Lesions are slow-growing, exophytic, or plaque-like tumors of the dermis and subcutis. They occur predominantly on the limbs and trunk of young and middle-aged adults.¹³⁹⁵ There is a female predominance.¹³⁹⁶ Occasionally, lesions have been associated with radiotherapy or chronic lymphedema. DNA sequences of HHV-8 have been detected in one case.¹³⁹⁷ Local recurrence is common, but metastasis to local lymph nodes has occurred in only one case. In another case, multiple lesions developed in noncontiguous sites during a 10-year period.¹³⁹⁸ The relationship of this tumor to endovascular papillary angioendothelioma of childhood (Dabska's tumor) is unclear, although they are histologically distinct.

Treatment is by wide local surgical excision to obtain clear margins because local recurrence is common. Radiation may be effective for recurrent lesions, but there is always the long-term risk of angiosarcoma following irradiation.

Histopathology¹³⁹⁴

The distinctive feature of this tumor is the pattern of arborizing vessels, which resembles the rete testis. Vessels are lined by 'hobnail', monomorphous endothelial cells that have scant cytoplasm and minimal or no atypia (Fig. 38.50). Mitoses are not seen. The tumor involves the dermis, subcutis, and, rarely, underlying muscle. A further characteristic is the presence of a prominent lymphocytic infiltrate, which may be so heavy as to almost obscure the vessels. As well as surrounding vessels, lymphocytes are also present in the lumina of vessels, closely applied to the endothelial cells. This feature, as well as the presence of occasional intraluminal papillae with collagenous cores, resembles Dabska's tumor. However, the cavernous lymphangioma-like appearance of Dabska's tumor contrasts with the thinner retiform spaces of retiform hemangioendothelioma.¹³⁹⁶ Their staining with the lymphatic marker D2-40 differs in most cases.¹³⁹⁹ Conspicuous papillary structures are rarely present.¹⁴⁰⁰ Some tumors also have solid areas with spindle cells arranged in closely packed cords with narrow vascular lumina. Endothelial cells express CD34, *Ulex europaeus*-1 lectin, CD31, and factor VIII-associated antigen. In a study of four cases, D2-40 was positive in one case, but three cases showed no staining at all.¹³⁹⁹ None expressed VEGFR-3.¹³⁹⁹ As stated previously, this contrasts with the usual positive staining in all cases of Dabska's tumor.¹³⁹⁹ Lymphocytes about the vessels are a mixture of B and T cells (CD20⁺, CD3⁺); those within the vessel are predominantly T cells (CD3⁺). A recent case that developed in a cystic lymphangioma on the shoulder and back of a 6-year-old girl, treated by the sclerosing agent Picibanil® (OK-432), showed microscopic features of both retiform hemangioendothelioma and Dabska's tumor (papillary intralymphatic angioendothelioma). Endothelial cells in this case were D2-40⁺.¹⁴⁰¹

Figure 38.50 Retiform hemangioendothelioma. There are arborizing vessels lined by hobnail endothelial cells. (H&E)

Dermoscopy of a case revealed a pinkish (milky red) background with a few dotted and linear vessels. Although not specific, the pinkish background is generally associated with malignant tumors, including cutaneous angiosarcoma, KS, and amelanotic melanoma, and its recognition should prompt performance of a biopsy.¹⁴⁰²

COMPOSITE HEMANGIOENDOTHELIOMA

Composite hemangioendothelioma is a rare, locally aggressive vascular tumor of low-grade malignancy showing varying combinations of benign, low-grade malignant, and malignant vascular components.¹⁴⁰³ Fewer than 20 cases have been reported. The predominant components are epithelioid hemangioendothelioma, retiform hemangioendothelioma, and spindle cell hemangioendothelioma.^{1403,1404} Cavernous hemangioma-like areas and angiosarcomatous elements are present in most cases. The lesions present as reddish-purple nodular lesions, uncommonly multifocal, on the extremities. The face and trunk are uncommon sites. Most lesions occur in adults, but three congenital cases have been reported.^{1404,1405} Lesions measure 1.5–30 cm in diameter.¹⁴⁰⁴ One case has arisen in Maffucci's syndrome.¹⁴⁰⁴

Local recurrence has been reported,^{1404,1406,1407} but metastasis is rare.^{1403,1408} Surgical excision with at least 2-cm margins is the treatment for resectable lesions. Inoperable and recurrent lesions can be treated with IFN- α -2b or chemotherapy.

Histopathology

The tumor usually infiltrates the dermis and subcutis. Muscle is involved in a few cases. As stated previously, there is a mixture of various types of vascular lesions. In the published cases, retiform areas have varied from 10 to 80% of the tumor. Epithelioid areas have averaged 10%, whereas spindle cell hemangioendothelioma has varied from 5 to 60% of the lesion, although in most cases it is less than 10%.^{1404–1406} Lymphatic differentiation also occurs. In one case, this took the form of PILA.¹⁴⁰⁸

All tumor cells express CD31, but CD34 is not usually expressed in epithelioid and retiform areas.¹⁴⁰⁶ In the one case in which it was tested for, the tumor cells expressed PROX-1, supporting a lymphatic line of differentiation.¹⁴⁰⁸ Surprisingly, D2-40 has not been mentioned, even in recent reports.

EPITHELIOID SARCOMA-LIKE CUTANEOUS HEMANGIOENDOTHELIOMA (PSEUDOMYGENIC HEMANGIOENDOTHELIOMA)

Epithelioid sarcoma-like cutaneous hemangioendothelioma presents as a subcutaneous nodule, often involving the distal extremities of young men. It consists of sheets of polygonal and fusiform tumor cells with only a slight suggestion of vasogenesis (Fig. 38.51).¹⁴⁰⁹ Cells comprising the epithelioid portion of the tumor possess abundant, brightly eosinophilic cytoplasm, similar to the appearance of rhabdomyoblasts. This neoplasm shows keratin immunoreactivity, as can be seen in approximately 30–40% of all epithelioid endothelial tumors, but it also exhibits positivity for CD31, FLI1, and INI1, unlike true epithelioid sarcoma. ERG, a member of the E26 transformation-specific (ETS) family of transcription factors expressed in endothelial cells, is also

Figure 38.51 Epithelioid sarcoma-like cutaneous hemangioendothelioma (pseudomyogenic hemangioendothelioma). There are sheets of moderately atypical tumor cells. There is only a vague suggestion of vasogenesis. These cells stained positively for cytokeratin and FLI1. (H&E)

positive in tumor cells.¹⁴¹⁰ Epithelioid sarcoma-like cutaneous hemangioendothelioma is prone to recur locally, but metastases are uncommon, again in contrast to the behavior of true epithelioid sarcoma. Because of the partial resemblance of this tumor to myogenic neoplasms, Hornick and Fletcher proposed renaming it pseudomyogenic hemangioendothelioma.¹⁴¹¹ Translocations between chromosomes 7 and 19 have been found in several cases.¹⁴¹²

MALIGNANT AND ATYPICAL GLOMUS TUMORS

Malignant glomus tumor (glomangiosarcoma) is a rare tumor of the skin and soft tissues that may arise *de novo* or in association with a benign glomus tumor.^{800,1413–1419} Approximately 50 cases have been reported.¹⁴²⁰ They occur at all ages and in both males and females. The lower extremities are the most commonly reported site, but they may also occur on the upper extremities, trunk, and face.¹⁴²⁰ They may occur in the superficial or deep soft tissues and measure up to 12 cm in diameter.¹⁶⁴

In 2001, Folpe *et al.* proposed histological criteria for malignancy based on a series of 52 histologically atypical glomus tumors.¹⁶⁴ A malignant glomus tumor should have a large size >2 cm and deep location or atypical mitotic figures or marked atypia with mitotic figures (5 mitoses/50 HPF). Approximately 1% of glomus tumors show features of malignancy.¹⁴²¹ A significant number of malignant cases (~40%) metastasize, and nearly one-third of patients will die from their disease.¹⁶⁴ Local recurrence also occurs.

Treatment is wide local excision with clear margins. Close follow-up is recommended, given the significant potential for aggressive behavior.

Histopathology

The tumor may be a solitary, relatively well-circumscribed lesion or a multilobular growth with pushing margins.^{164,800} A conventional glomus tumor may be present. Nests and sheets of cells surround ectatic, branching blood vessels. It resembles to varying degrees a typical glomus tumor, but the cells usually show intermediate to high nuclear grade and significant mitotic activity (Fig. 38.52). There may be a frankly malignant, spindle cell component, with cigar-shaped hyperchromatic nuclei and pale eosinophilic cytoplasm.^{1418,1421,1422} A small cell component is sometimes present.

Several variants of histologically atypical glomus tumors exist, including the *symplastic glomus tumor*, with the same abnormal nuclear features seen in other symplastic tumors; *glomus tumors of uncertain malignant potential*; and *glomangiomas*. The features of these variants are listed in Table 38.1, which is based on the article by Folpe *et al.*¹⁶⁴

Immunohistochemistry shows diffuse membranous staining for collagen type IV. There is both membranous and cytoplasmic staining for smooth muscle actin.^{1420,1421} The tumor cells are negative for S100 protein, HMB-45, CD34, CD31, cytokeratin, EMA, and desmin.¹⁴²³

TUMORS WITH A SIGNIFICANT VASCULAR COMPONENT

Some tumors of mesenchymal derivation may have two or more components, one of which may be of vascular type. These tumors are considered in detail elsewhere, but they are mentioned here briefly for completeness:

- Angiofibromas
- Angioleiomyoma
- Angiolipoma
- Spindle cell lipoma (angiomatoid variant)

Figure 38.52 Malignant glomus tumor. (A) Normal glomus tumor is present along one edge. (B) The malignant component is quite cellular with mitotic figures. (H&E)

Table 38.1 Classification of atypical glomus tumors	
Malignant glomus tumor	Deep location; size >2 cm; atypical mitotic figures; moderate to high nuclear grade
Symplastic glomus tumor	High nuclear grade without other malignant features
Glomus tumors of uncertain malignant potential	Lack criteria of above two categories; high mitotic activity and superficial location only, or large size only, or deep location only
Glomangiomas	Diffuse angiomas and excess glomus cells

Source: From Folpe AL, Fanburg-Smith JC, Miettinen M, Weiss SW: Atypical and malignant glomus tumors: Analysis of 52 cases, with a proposal for the reclassification of glomus tumors. *Am J Surg Pathol* 2001; 25: 1–12.

- Angiomyolipoma
- Angiomyxoma
- Angiomyofibroblastoma
- Dermatofibroma–aneurysmal variant
- Angioplasmocellular hyperplasia.

The multinucleate cell angiohistiocytoma has been included in this category in some classifications. It has been considered here with the vascular proliferations (see p. 1095).

ANGIOFIBROMAS

The angiofibromas are a clinically diverse group of entities that share similar histological features, namely the presence of small vessels of capillary type with a collagenous stroma containing some spindle cells. Multinucleate cells are sometimes present. Examples include fibrous papule of the face, adenoma sebaceum, pearly penile papules, acral fibrokeratomas (the vessels are often not prominent), and familial myxovascular fibromas (see p. 968).

ANGIOLEIOMYOMA

The angioleiomyoma usually presents as a solitary nodule on the extremities, particularly the lower legs (see p. 1031). They are well-circumscribed lesions composed of interlacing bundles of smooth muscle arranged around and between vascular channels. The vessels vary in size from large sinusoidal vessels to small slit-like channels.

ANGIOLIPOMA

Angiolipomas are subcutaneous tumors with a predilection for the extremities, particularly the forearm (see p. 1019). Mild pain or discomfort is sometimes present. They are composed of lobules of mature fat, admixed with capillaries that may comprise 5–50% or more of the lesion.

SPINDLE CELL LIPOMA (ANGIOMATOID VARIANT)

Some spindle cell lipomas have areas resembling a lymphangioma or hemangiopericytoma. Another variant has irregular and branching spaces with villiform connective tissue projections giving a striking angiomatoid appearance. This is the so-called ‘angiomatoid’ or ‘pseudoangiomatous variant’ (see p. 1022).

ANGIOMYOLIPOMA

The angiomyolipoma is a rare tumor resembling an angioleiomyoma with the admixture of foci of mature fat cells of varying size between the muscle bundles (see p. 1032). The blood vessels resemble those seen in angioleiomyomas.

ANGIOMYXOMA

The superficial angiomyxoma usually involves the dermis and subcutis. It is composed of spindle-shaped and stellate cells set in a basophilic myxoid matrix containing numerous small blood vessels. Epithelial strands or keratin-filled cysts are present in more than half (see p. 1012).

ANGIOMYOFIBROBLASTOMA

Angiomyofibroblastoma is a rare tumor of the vulva composed of an edematous stroma containing abundant blood vessels, predominantly of the capillary type (see p. 982). Spindle cells are present in the stroma, often aggregated around the vessels.

DERMATOFIBROMA (ANEURYSMAL VARIANT)

Rarely, a dermatofibroma is composed of such large vascular spaces that it can be confused at first glance with a vascular tumor. The stroma, which is composed of spindle cells, often in a storiform arrangement, contains abundant hemosiderin (see p. 993).

ANGIOPLASMOCELLULAR HYPERPLASIA

Angioplasmocellular hyperplasia is an exceedingly rare condition characterized by a proliferation of small blood vessels, some with

vacuolated endothelium, and a mixed inflammatory cell infiltrate with a predominance of polyclonal plasma cells (see p. 1141).

INTRODUCTION

Virtually any tumor can metastasize to the skin, but some do so more often than others.¹ The identification of the primary site is not always easy, and this process is further complicated by the occurrence of primary adnexal tumors of the skin that mimic various metastases. Immunohistochemistry has assisted in the specific diagnosis of these tumors, but it should be remembered that the specificity of a particular marker declines with successive studies.

Metastasis represents the end stage of a complex series of interactions between the tumor cells and the host tissues.^{2,3} There are many factors that influence the localization of metastases other than the natural lymphatic and vascular connections of the primary tumor. In the past, the concept of 'favorable soil' and 'unfavorable soil' was invoked in an attempt to explain why certain organs were only rarely involved by metastases. There are now some scientific explanations available to account for the 'unfavorable soil' of some organs, although none has been advanced that explains satisfactorily why the skin generally is an uncommon site for visceral metastases. The vascularity of the scalp may explain why this is sometimes a favored site. The tumor cells may reach the skin by direct invasion from an underlying tumor, by accidental implantation during a surgical or diagnostic procedure, and by lymphatic and hematogenous spread.

Based on several large autopsy series of patients with visceral cancer, the incidence of cutaneous metastases is approximately 2% of all cases.² The usually quoted range from several different studies is 1.2–4.4%.^{4,5} A retrospective study in 1993 of 4020 patients with metastatic disease found that 10% had cutaneous metastases.⁶ A study of 3827 autopsies carried out between 1914 and 1943, but published in 2008, found that 6% had cutaneous metastases.⁷ The breast accounted for more than half of these metastases.⁷ In one series, the skin was the 18th most frequent metastatic site for all tumor types.⁸

Although it has little relevance to cutaneous metastasis, the Halstedian hypothesis of cancers arising in an organ, spreading to the regional area, and subsequently metastasizing is no longer tenable.⁹ Widespread metastases can develop despite extensive loco-regional treatment.⁹ Perhaps this has relevance to the management of melanoma.

Many generalizations can be made about cutaneous metastases. These relate to the time interval between their manifestation and the diagnosis of the primary tumor, their clinical appearance, their location, the site of origin of the primary tumor, and their prognostic significance.¹⁰ These aspects are considered next, followed by an account of the cutaneous metastases derived from various viscera.

CLINICAL AND MORPHOLOGICAL FEATURES

Time of development

Cutaneous metastases may be the first indication of a visceral cancer,¹¹ with the incidence in one series being 0.8%.¹² These **precocious metastases** are particularly likely to present at the umbilicus or, less frequently, on the scalp. The kidney,¹³ lung,¹⁴ thyroid,¹⁵ and ovary¹¹ are organs whose tumors may present in this way.¹⁶

With most tumors, the metastases develop some months or years after the primary malignancy has been diagnosed¹¹ – so-called '**metachronous metastases**'. In approximately 7% of cases, this interval exceeds 5 years. Tumors of the breast and kidney and malignant melanomas may give rise to delayed metastases.¹⁷

The term '**synchronous metastasis**' is used when the cutaneous metastasis and the primary tumor are diagnosed simultaneously.¹⁸ This sometimes occurs with tumors of the breast and oral cavity.

Clinical aspects

Cutaneous metastases are more likely to be found in older individuals.¹⁹ In neonates, they are usually derived from a neuroblastoma or, less commonly, from a rhabdomyosarcoma.²⁰ Metastases from germ cell and trophoblastic tumors, although rare in the skin, develop there particularly in young adults.

Cutaneous metastases usually present as multiple, discrete, painless, freely movable nodules of sudden onset.^{6,16,21} They usually show rapid enlargement.²² Sometimes several small nodules are localized to one area.²³ Solitary metastases occur in approximately 10% of cases. The nodules are usually 1–3 cm in diameter. Much larger lesions and also occult lesions have been recorded.^{24,25} They vary in color from red to bluish-purple to light brown or flesh colored. Occasionally, plaques are formed. One variant of this form develops in the scalp as patches of alopecia (alopecia neoplastica), sometimes resembling alopecia areata.^{26–30} Cicatricial plaques also form: metastases from the breast,^{26,27} lung, and kidney may give this pattern on rare occasions.

There are isolated reports of other patterns of cutaneous metastases.⁵ For example, they may resemble erythema annulare,⁵ a chancre,³¹ a hematoma,³² an epidermal cyst,³³ a condyloma,⁵ or an ulcer.⁵ They may present in a zosteriform or target-like pattern.^{34–48} In one case, herpes zoster was associated with the metastases.⁴⁹ Elephantiasis of the lower limbs due to lymphatic obstruction and facial or eyelid lymphedema are rare clinical presentations.^{50–52} Metastases have also been reported in an area of radiation dermatitis.⁵³

Three clinical patterns of metastasis are almost exclusively related to carcinomas of the breast: carcinoma erysipelatoides ('inflammatory carcinoma'), carcinoma telangiectaticum, and carcinoma en cuirasse.^{19,54–59} The *inflammatory pattern* presents as a large, tender, warm plaque that may resemble erysipelas.^{17,54,60} It is found in less than 2% of all breast carcinomas. Some regard this as being due to direct extension from the underlying carcinoma and not a true metastasis.¹⁶ Rarely, this pattern is seen with metastases from melanoma⁶¹ and mesothelioma⁶² and from carcinomas of the esophagus,⁶³ stomach,⁶⁴ pancreas,⁶⁵ colon,^{59,66} rectum,^{67,68} prostate,⁵⁵ bladder,⁶⁹ and lung.^{35,70} It follows the obstruction of lymphatics at all levels of the dermis, with resulting edema.⁶⁰ There are often some perivascular and perilymphatic inflammatory cells. *Carcinoma telangiectaticum* presents as a telangiectatic sclerotic plaque, often studded with pink papules and pseudovesicles.^{54,71} There is massive subepidermal edema resulting from obstruction by tumor of small blood vessels and lymphatics in the upper dermis. Other vessels are congested. Rarely, metastases from the lung will give this picture. *Carcinoma en cuirasse* is a diffuse induration of the breast resulting from some dermal fibrosis and a diffuse infiltrate of tumor cells between collagen bundles, sometimes in an 'Indian-file' pattern.⁵⁴

Location of metastases

Metastases tend to occur on the cutaneous surfaces near the site of the primary tumor, although there are many exceptions.⁶ Metastases from tumors of the lung often involve the chest wall and proximal parts of the upper extremities, whereas those from the oral cavity and esophagus may metastasize to the head and neck, and those from the gastrointestinal and genitourinary systems may metastasize to the abdominal wall.^{23,72} Approximately 5% of metastases involve the scalp.^{6,11,73} This is a common site for metastases from the thyroid.⁷⁴ In a series of 398 Taiwanese patients with malignant cutaneous tumors of the scalp, metastatic tumors accounted for 51 of these cases; 18 of these 51 cases were from the lung.⁷⁵

Metastasis to the umbilicus is also quite common.^{76,77} The lesion that results has been called the **Sister Mary Joseph nodule** in recognition of a nursing superintendent at the Mayo Clinic, Rochester, Minnesota, who is credited with recognizing the clinical significance of these

Figure 39.1 Umbilicus: Sister Mary Joseph's nodule. The dermis is replaced by metastatic carcinoma of ovarian origin. (H&E)

nodules.⁷⁷ The underlying primary tumor is usually an adenocarcinoma of the stomach, large bowel, ovary, pancreas, gallbladder, endometrium, or breast (**Fig. 39.1**).^{76–81} Rare primary tumors have included transitional cell carcinoma of the bladder,⁸² a peritoneal mesothelioma,⁸³ a carcinoid, and a leiomyosarcoma of the intestine. In one case, the umbilical tumor resembled an ovarian serous papillary tumor, but no ovarian tumor was ever found.⁸⁴ Other rare sites are listed in the review of all cases reported between 1960 and 1995.⁸⁵ Leukemia cutis rarely presents in this way.⁸⁶ Sister Mary Joseph nodules are usually solitary and firm, sometimes with surface fissuring. In 12 of a series of 85 cases reported in 1984, the umbilical nodule was the initial presentation of the tumor.⁷⁷ There are various routes by which tumor cells can reach the umbilicus, including contiguous extension and spread by lymphatic and venous channels, often associated with embryological vestiges in this region.⁷⁷

The penis may be the site of metastases from the bladder and prostate.^{87,88} The deposits are usually multiple and sometimes associated with priapism.⁸⁷ Metastatic tumors involving the vulva are rare, although 66 cases were reported from one institution (the M. D. Anderson Cancer Center) in 2003.⁸⁹ In 29 cases, the site of origin was non-gynecological, whereas in 31 cases the primary was in a gynecological site, with 15 of these being in the cervix. The primary site was unknown in 6 cases.⁸⁹

The lower extremities, excluding the thighs, are uncommonly involved with metastases.¹¹ Other rare sites include the nail bed,^{90,91} thumb, finger,⁹² big toe,⁹³ scrotum, eyelid, eyebrow, nasal tip, and ear.^{2,5,94–97}

Cutaneous metastases may develop at the site of a surgical or diagnostic procedure.^{2,98–100} Metastases are sometimes seen in abdominal, perineal, mastectomy, and nephrectomy scars; around colostomy sites; and along the tract produced by a thoracentesis needle. However, seeding along the needle tract is unexpectedly rare following percutaneous biopsy of prostatic carcinomas.¹⁰¹ Metastases to soft tissue are beyond the scope of this book.¹⁰²

Metastasis to a nevocellular nevus is a rare event.^{103,104}

Sites of the primary tumor

The detailed studies of Brownstein and Helwig (1972) have provided valuable information regarding the most frequent sites of origin of the tumors that give rise to cutaneous metastases.⁷² They studied 724 patients in whom there was histopathological confirmation of both the

primary tumor and the secondary deposit in the skin. Their studies complement the earlier report by Gates in 1937.⁹⁴

The most frequent primary tumors in men were carcinoma of the lung (24%), carcinoma of the large intestine (19%), melanoma (13%), and squamous cell carcinoma of the oral cavity (12%).⁷² In women, they were carcinoma of the breast (69%), carcinoma of the large intestine (9%), melanoma (5%), and carcinoma of the ovary (4%).⁷² A study from India in 1988 showed that the lung and esophagus were the most common sites of the primary tumor in men and the breast and ovary in women.¹⁰⁵ Breast cancer and melanoma were the most common origins for skin metastases in the study of 4020 patients with metastatic carcinoma,⁶ a finding repeated in a report from Spain.²² A study in 2004 from a large Veterans Administration hospital in the United States showed that the lung, melanoma, and gastrointestinal tract were the three most common primary sites of cutaneous metastases.¹⁰⁶

Sometimes, despite exhaustive investigations, no primary lesion can be identified.¹⁰⁷ This may result from an extremely small primary tumor or its regression.

Prognostic aspects

The development of cutaneous metastases is usually a grave prognostic feature because dissemination to other organs has usually already occurred. The average survival time after the appearance of cutaneous metastases is 3–6 months,²³ although this has improved slightly in recent times.⁶ However, there are many reports of patients with carcinoma of the breast, neuroblastoma, and other tumors¹⁵ who survived many years after the appearance of the cutaneous metastases.

Histopathological features

More than 60% of metastases are adenocarcinomas, usually arising in the large intestine, lung, or breast.^{6,17,23} If the glandular structures are well differentiated, the colon or rectum should be suspected as the primary site. Tumors from the breast usually have a very undifferentiated pattern, with sheets of cells or sometimes columns between the collagen bundles. Signet-ring cells can be found in some metastases of mammary origin, but they are more usual in secondary deposits of gastric origin.¹⁰⁸

Approximately 15% of metastases are of squamous cell type. They usually arise from the oral cavity, lung, or esophagus. The remainder of cutaneous metastases are melanomas, anaplastic tumors, or other rare specific patterns.¹⁰⁹

Metastases usually resemble the primary tumor, although the features are sometimes more anaplastic.²³ The metastases from a clear cell renal cell carcinoma can appear disarmingly benign:¹¹⁰ a mistaken diagnosis of a benign appendage tumor may be made in these circumstances (**Fig. 39.2**). Clear cell hidradenoma shows a vesicular to finely vacuolated cytoplasm, in contrast to the sometimes granular cytoplasm seen in renal cell carcinoma.¹⁰⁹

Metastases are centered on the dermis, although there is sometimes extension into the subcutis. The epidermis is usually intact, and there is an underlying narrow zone of compressed collagen separating the tumor from the epidermis (grenz zone). Occasionally, a metastatic squamous cell carcinoma will touch the undersurface of the epidermis, making distinction from a primary carcinoma difficult.¹¹¹ Epidermotropic metastases are exceedingly rare, except for cutaneous melanomas.¹¹² This has also been seen in carcinomas of the prostate and breast, and it has recently been reported in vulvar squamous cell carcinoma.¹¹³ Transepidermal elimination of metastatic breast cancer has also been described recently.¹¹⁴ Dermal sclerosis is uncommon, but it can be seen with some breast carcinomas.

Lymphatic permeation is a prominent feature of the so-called 'inflammatory carcinomas' (see p. 1118). It is sometimes present at

Figure 39.2 Metastatic renal cell carcinoma in the skin. A mistaken diagnosis of eccrine hidradenoma is sometimes made in such a case. (H&E)

Figure 39.3 Metastatic adenocarcinoma with widespread lymphatic permeation. (H&E)

Figure 39.4 Lymphatic permeation in another case of metastatic adenocarcinoma. (H&E)

the edge of a cutaneous metastasis. Uncommonly, lymphatic channels throughout the dermis are involved (Figs. 39.3 and 39.4).

Immunohistochemistry is of increasing value in the interpretation of cutaneous metastases.^{109,115} Monoclonal antibodies against thyroglobulin, calcitonin, prostatic antigens, leukocyte common antigen (CD45), epithelial membrane antigen, S100 protein, neuron-specific enolase, various cytokeratins, vimentin, and desmin can be used to elucidate or confirm the nature of the primary tumor that gave rise to the cutaneous metastasis. A truncated immunohistochemical battery using cytokeratin 7 (CK7), CK20, and S100 protein has been recommended as a starting point in the assessment of a suspected cutaneous metastasis;¹⁰⁶ often, they need to be combined with other markers.¹¹⁶ A different panel, including p63, B72.3, calretinin, and CK5/6, has been used to differentiate metastatic carcinoma from primary skin adnexal tumors.¹¹⁷ The majority of primary adnexal tumors express p63, whereas cutaneous metastases from internal adenocarcinomas are usually negative.^{118–120} In a more recent study, p63 was positive in 5 of 45 (11%) cutaneous metastases.¹²¹ Podoplanin (using the D2-40 antibody) is useful in distinguishing primary cutaneous adnexal carcinomas from adenocarcinomas metastatic to the skin, with a high degree of sensitivity (94.5%) and specificity (97.2%).¹²² This investigative field is expanding rapidly, with many new markers appearing.

SPECIFIC METASTASES

Breast

The anterior chest wall is commonly involved by recurrences of carcinoma of the breast, although distant cutaneous metastases are uncommon.^{123,124} In his review of cutaneous metastases, Rosen mentions two autopsy series of carcinoma of the breast in which cutaneous metastases were found in 18.6 and 37.7% of cases, respectively.² Brownstein and Helwig, in their study of 724 patients with cutaneous metastases, recorded 168 cases in women with carcinoma of the breast (69% of the total number of women in the series) and 9 in men.⁷² In 20 of these, there were single distant metastases; in 3, there were multiple metastases.⁷² In the remainder, only the chest wall was involved. Extensive cutaneous metastases are sometimes observed with carcinoma of the breast, in both males and females.^{125–128}

The scalp is a favored site of distant metastases,¹²³ but the thigh may also be involved.¹²⁹ Patches of alopecia resembling alopecia areata (alopecia neoplastica) may result.^{26–28,130–134} Other clinical patterns found on the chest wall include the so-called ‘inflammatory carcinoma’,^{55–58,135} carcinoma telangiectaticum,¹³⁶ and carcinoma en

cuirasse.^{54,137,138} Pigmented metastases mimicking malignant melanoma have also been reported.^{139,140} Prolonged survival has been recorded after the appearance of the cutaneous lesions.^{131,141}

Carcinoma of the inframammary crease is an uncommon but distinctive pattern of presentation that results from early invasion of the skin by a peripherally situated tumor.^{142,143} It is exophytic and fissured and may simulate a primary epidermal tumor both clinically and microscopically.¹⁴⁴

Histopathology

The histopathology is usually that of a poorly differentiated adenocarcinoma (Fig. 39.5). There may be sheets or large clusters of tumor cells in the dermis. Sometimes the cells are in linear array between the collagen bundles, resulting in an ‘Indian-file’ pattern.⁷² Rarely, the cells resemble those seen in a granular cell tumor¹⁴⁵ or have a sarcomatous appearance.¹⁴⁶ Lymphatic permeation may be prominent, particularly in those with an inflammatory or telangiectatic clinical pattern.¹³⁵ Prominent epidermotropism has been reported; the pattern mimicked Paget’s disease and melanoma.^{147,148} Sclerosis of dermal collagen is sometimes present, particularly in the scalp lesions associated with alopecia neoplastica.²⁷ Rarely, intraepidermal vesicles form, secondary

to prolonged lymphatic obstruction.¹⁴⁸ Tumor cells have been seen in these vesicles.¹⁴⁹

Occasionally, only scattered small tumor cells are present in the dermis, and these cells may be difficult to distinguish from inflammatory cells.⁷² Epithelial membrane antigen, CK7, and some newer mammary-specific antigens are detectable on these cells by immunoperoxidase methods. Gross cystic disease fluid protein-15 (GCDFP-15), estrogen receptor (ER), and progesterone receptor (PR) proteins are valuable markers for cutaneous metastatic breast carcinoma when used in combination.^{148,150,151} In one series of cutaneous metastases from breast cancers, the following profiles were obtained: CK7 (66%), CK19 (91%), ER (50%), PR (42%), carcinoembryonic antigen (CEA) (73%), E-cadherin (55%), and Ber-EP4 (27%).¹⁵¹ All metastases were negative for CK20, CK5/6, CD10, and thyroid transcription factor-1 (TTF1).¹⁵¹ It should be remembered that an occasional carcinoma of the breast will have S100+ cells or contain melanin pigment,¹⁵² which could lead to a mistaken diagnosis of malignant melanoma. Breast cancer cells strongly express cathepsin B.¹⁵³ ER, PR, and HER-2/neu markers show significant concordance between primary and metastatic carcinoma of the breast.¹⁵⁴ A summary of the immunohistochemical profile is presented in Table 39.1. Metastasis to a benign intradermal nevus has also been reported.¹⁰³

Figure 39.5 Metastatic carcinoma of breast origin. The tumor cells are arranged in an ‘Indian-file’ pattern. (H&E)

Lung

Cutaneous metastases are found in 4% or less¹⁵⁵ of patients with carcinoma of the lung. In a small number of cases, these are precocious metastases.¹⁴ The chest wall and abdomen are the usual sites, although ‘oat-cell’ (small cell) carcinomas appear to have a predilection for metastasizing to the back (Fig. 39.6).¹⁸ The finger and skull are extremely rare sites.^{156,157} Rarely, an inflammatory or zosteriform pattern is produced. Death usually occurs within 3 months of the development of the skin lesions. Eyelid edema, secondary to superior vena cava syndrome, can be the presenting sign of a primary bronchogenic carcinoma.¹⁵⁸ The histopathological pattern is squamous cell carcinoma in 40%, adenocarcinoma in 20%, and undifferentiated carcinoma in 40%.^{18,159,160} One bronchiolar and one mucoepidermoid bronchial carcinoma were among the tumors of lung reported by Brownstein and Helwig in their review on cutaneous metastases.⁷² Fetal adenocarcinoma of the lung with preceding cutaneous metastasis and basaloid carcinoma of the lung presenting concurrently with cutaneous metastasis have been reported.^{161,162} Pleural mesotheliomas rarely metastasize to the skin.^{62,163–166} Metastasis to the lip was the initial presentation of mesothelioma in two cases.¹⁶⁷ The cells stained with CK5/6, epithelial membrane antigen, HBME1, calretinin, and CK7.¹⁶⁷

TTF1, expressed in epithelial cells of thyroid and lung, is often expressed in cutaneous metastases of lung tumors.¹⁵¹ It is not present

Table 39.1 Immunohistochemical profile of cutaneous breast metastases	
CK7	Positive in two-thirds of cases
CK20	Negative
CK5/6	Negative
Estrogen receptor	Positive in 50%; high specificity
Progesterone receptor	Positive in nearly half; high specificity
GCDFP-15	Positive in 90% of lobular tumors with signet-ring cells, 70% of ductal carcinomas, but positive in some salivary gland and adnexal tumors
CEA	Positive in nearly 75%
S100	Positive in rare cases

Figure 39.6 Metastatic carcinoma of lung – small cell ('oat cell') carcinoma. This metastatic lesion was located on the back. (H&E)

Table 39.2 Immunohistochemical profile of lung metastases	
CK5/6	Squamous cell carcinoma positive, mesothelioma positive, adenocarcinoma negative
CK7	Adenocarcinoma positive, squamous cell carcinoma negative, small cell negative
CK20	Squamous cell carcinoma negative, adenocarcinoma negative, small cell negative but Merkel cell carcinoma positive
TTF1	Adenocarcinoma positive, squamous cell carcinoma negative, small cell positive but thyroid also positive
CAM5.2 (CK8/18)	Small cell dot positivity
Ber-EP4	Adenocarcinoma positive, small cell positive
CEA	Adenocarcinoma positive, squamous cell carcinoma negative

in Merkel cell carcinomas. The immunohistochemical profile of lung metastases is shown in [Table 39.2](#).

Oral cavity and gastrointestinal system

Tumors of the oral cavity usually spread to the face or neck.⁷² In some instances, this results from direct extension of the tumor rather than true metastasis.¹⁶ The tumors are usually squamous cell carcinomas. Less than 2% of *esophageal carcinomas* metastasize to the skin.¹⁸ The primary lesion is usually a squamous cell carcinoma in the lower esophagus;¹⁸ metastatic adenocarcinoma is sometimes seen.^{168,169} The metastases are multiple nodules with a predilection for the upper part of the trunk and the neck. Acral metastases, and metastases to the breast, masquerading as an inflammatory breast carcinoma have been recorded.^{63,170} Squamous cell carcinomas of the esophagus are usually CK5/6⁺.¹⁵¹ Brownstein and Helwig reported 29 cases of *gastric carcinoma* with metastasis to the skin.⁷² The trunk, particularly the umbilical area, is a favored site.^{77,171,172} The tip of the finger,^{92,173} the face,¹⁷⁴ the axilla,¹⁷⁵ and a congenital nevus on the occiput¹⁰⁴ are uncommon sites of involvement. The tumors are usually poorly differentiated adenocarcinomas.

Figure 39.7 Metastatic colonic adenocarcinoma. This nodule from the eyelid shows a metastatic adenocarcinoma with luminal necrotic material and debris ('dirty necrosis'). (H&E)

Table 39.3 Immunohistochemical profile of gastrointestinal metastases	
CK5/6	Esophagus positive, other sites negative
CK7	Esophagus negative, gastric some positive, colorectal negative
CK20	Esophagus negative, gastric positive, colorectal positive
CEA	Gastric positive, colorectal positive
Ber-EP4	Esophagus and mouth positive
HIK1083	Gastric positive, adnexal carcinomas negative

Signet-ring cells and extracellular mucin pools may be present.¹⁷⁴ Eczematous and erythematous lesions on the face, resulting from cutaneous metastases, have also been reported.^{176,177} A monoclonal antibody HIK1083 specific for gastric O-glycan can be used in differentiating a cutaneous metastasis of gastric carcinoma from primary sweat gland carcinoma in which it is negative.¹⁷⁸ This stain is superior to CK20, which while often present in metastatic carcinomas of skin, is also found in metastatic colorectal cancer and occasional metastases from the lung and breast.¹⁷⁸ The *colon* is a common source of cutaneous metastases. Brownstein and Helwig recorded 90 males and 22 females in this category.⁷² This makes it the second most common primary site in both males and females. Brady *et al.* reported a 3.5% incidence of cutaneous metastases in patients coming to autopsy with adenocarcinoma of the colon and rectum.¹⁸ The metastases are usually multiple and metachronous, and most often they are in the skin of the abdominal wall or perineal region.^{18,68,72} The umbilicus, or the colostomy site, may be involved.^{77,179–181} The appearance of multiple metastases is a poor prognostic sign. The deposits are usually composed of well-differentiated adenocarcinoma, although mucinous, less well-differentiated variants are found. The metastases are typically 'dirty', with some neutrophils and degenerate cells in the lumina of the glands ([Fig. 39.7](#)). *Peritoneal mesotheliomas*, metastatic to the umbilicus, have been reported.^{83,182} The immunohistochemical profile of gastrointestinal metastases is listed in [Table 39.3](#).

Liver, pancreas, and gallbladder

Cutaneous metastases occur in nearly 3% of patients with malignant hepatomas of the *liver*.^{183–185} Rarely, it is the presenting manifestation,^{186,187} although death still follows in several weeks.¹⁸⁴ A 12-year-old child with cutaneous metastases on the thorax and epigastrium has been reported.¹⁸⁸ In another case, a metastasis to the gingiva mimicked a pyogenic granuloma.¹⁸⁹ The histopathological pattern may be either a cholangiocarcinoma or a hepatocellular carcinoma.^{184,190–193} A sarcomatoid carcinoma is extremely rare.¹⁹⁴ An immunohistochemical marker of hepatocellular differentiation is now available for use on paraffin sections (Hep Par 1).¹⁹⁵

Brownstein and Helwig recorded 15 cases of metastatic *pancreatic carcinoma* involving the skin.⁷² The umbilicus is a favored site for these metastases.^{76,196–198} Rarely, an inflammatory or epidermotropic pattern is present.^{65,199,200} Metastasis to the skin from a vasoactive intestinal polypeptide tumor (VIPoma) of the pancreas has been reported.²⁰¹

There are several reports in which the primary tumor was in the *gallbladder*.^{202–205} Rarely, the metastasis in such cases is to the umbilicus.^{77,78}

Kidney

Metastases have been reported in the skin in 2.8–6.3% of renal carcinomas.¹⁸ They accounted for 6% of the cutaneous metastases in males and 0.5% in females in the series of Brownstein and Helwig.⁷² As such, they rank after breast, lung, gastrointestinal tract, and melanoma in order of frequency.⁷² The metastases are solitary in 15–20% of cases.^{91,110,206} The head, particularly the scalp, is a common site of involvement.^{110,206,207} They may also be found in nephrectomy scars and the external genitalia.²⁰⁶ The metastases are sometimes precocious. Metachronous metastases usually appear within 3 years of the nephrectomy,⁷² although an interval of 23 years has been recorded.¹¹⁰ The deposits can be quite vascular, and they even resemble a pyogenic granuloma²⁰⁸ or Kaposi's sarcoma.²⁰⁹

Most cases are clear cell renal cell carcinomas in which the cells contain considerable glycogen and some fat (**Fig. 39.8**).^{110,210} Mitoses are sparse. There is usually extravasation of blood, with subsequent deposition of hemosiderin in the stroma. Metastasis to the skin of a transitional cell carcinoma of the renal pelvis^{211,212} and of a Wilms' tumor is occasionally reported.¹¹⁰

Figure 39.8 Metastatic renal cell carcinoma. Note the tubular arrangement of metastatic clear cells. (H&E)

A renal cell carcinoma marker (RCC-Ma), a monoclonal antibody to a proximal tubule antigen, is positive in nearly two-thirds of cutaneous metastases of renal cell carcinomas.²¹³ It is highly specific for this tumor and is not expressed by other clear cell tumors of the skin.²¹³ The cells often express epithelial membrane antigen.²¹⁴ Less than 10% of conventional renal cell carcinomas express CK7 or CK20.²¹⁵ The transcription factor PAX-2 is also useful for diagnosing metastatic renal cell carcinoma, and it is positive in a high percentage of clear cell, papillary, and collecting duct metastatic tumors.²¹⁶ The immunohistochemical profile of renal metastases is shown in **Table 39.4**.

Bladder and urethra

Cutaneous metastases from carcinomas of the urinary *bladder* are rare,^{82,217,218} ranging from 0.18%²¹⁹ to 1.8%.¹⁸ Brownstein and Helwig reported only 10 cases in their review of 724 patients with cutaneous metastases.⁷² The *urethra* is more rarely the primary site.^{217,220} Most patients die within months of the diagnosis of a skin metastasis.²²¹

Metastases from the bladder are usually multiple and at a single site.¹⁸ When solitary, they may be confused with primary skin cancers.²²² The upper extremities, trunk, abdomen, scrotum, and penis are the usual sites.^{190,217} Rarely, they are zosteriform or herpetiform in distribution.^{223,224} The tumors are transitional cell carcinomas or anaplastic carcinomas that may show areas of squamous differentiation (**Fig. 39.9**).^{220,225,226}

Immunohistochemistry is positive for the cytokeratin markers CK7, CK19, and CK20. Nearly half of transitional cell carcinomas are also CK14+.²²⁷

Table 39.4 Immunohistochemical profile of renal metastases	
CK7	Negative, but transitional cell tumors positive
CK20	Negative, but transitional cell tumors positive
RCC	Positive in two-thirds or more
Vimentin	Positive
CD10	Positive
PAX-2	Positive

Figure 39.9 Metastatic carcinoma of the bladder. This is a poorly differentiated tumor, in which neoplastic cells are concentrated near a follicular unit. (H&E)

Figure 39.10 Metastatic carcinoma of the prostate. The epidermis is spared in this example. (H&E)

Figure 39.11 Metastatic carcinoma of the ovary. The configuration is that of a well-differentiated adenocarcinoma. (H&E)

Male genital system

In one study of 321 metastatic lesions in 176 autopsy cases of *carcinoma of the prostate*, 4 lesions metastatic to the skin were found.²²⁸ Brownstein and Helwig recorded only 5 cases in their large series.⁷² The metastases are usually firm violaceous nodules, although unusual clinical patterns⁸⁷ such as Sister Mary Joseph nodules (see p. 1118),^{77,229,230} penile deposits,^{87,88,231–233} metastasis to a gynecomastic breast,²³⁴ a zosteriform pattern,³⁴ and a nodule simulating a sebaceous cyst³³ or an angiosarcoma^{235,236} have been recorded. Most metastases are in the inguinal region,²³⁷ but other sites have been reported.²³⁸ The primary tumor is usually an adenocarcinoma (Fig. 39.10),^{239,240} but one transitional cell carcinoma has been documented.²⁴¹ An example has been described of metastatic prostatic carcinoma to the skin, with an intraepidermal pagetoid component resembling extramammary Paget's disease.²⁴² Immunoperoxidase staining for prostate-specific antigen is a useful technique for confirming the prostatic origin of these metastatic adenocarcinomas.^{243–245}

There are several reports of cutaneous metastases from *testicular tumors*.²⁴⁶ The histopathological pattern has included seminoma,²⁴⁶ teratocarcinoma,²⁴⁷ and choriocarcinoma.^{23,248–250} There is one report of cutaneous metastases in the suprapubic region from an adenocarcinoma of the rete testis.²⁵¹ Primary cutaneous germ cell tumors of the skin and subcutis are exceedingly rare. Only two cases have been reported in adults, although a few more have been reported in young children.²⁵²

Squamous cell carcinomas of the *penis* rarely give rise to cutaneous metastases.¹⁷

Female genital system

Cutaneous metastases are found in approximately 2% of patients with fatal *ovarian carcinoma*.¹⁸ Brownstein and Helwig recorded 10 cases, which represents 4% of the cutaneous metastatic lesions in females.⁷² There are usually multiple nodules at a solitary site on the chest or abdomen. The umbilicus and thighs may be involved.^{253,254} The pattern is usually that of a well-differentiated adenocarcinoma (Fig. 39.11), sometimes having a papillary configuration with psammoma bodies.⁷² A carcinoma of mucinous pattern and a Brenner tumor²⁵⁵ have also been reported. Paraneoplastic associations such as dermatomyositis may be a presenting sign of ovarian carcinoma. These associations were

reviewed in 2008.²⁵⁶ Ovarian tumors are usually CK7⁺ and CK20[−], but some mucinous ovarian tumors may be CK20⁺.^{116,257}

Cutaneous metastases are unusual in *carcinoma of the cervix*^{97,258–260} and *uterine body*,^{261–265} even in the terminal phases.^{266,267} They usually involve the lower abdomen, groin, upper thighs,^{268,269} or umbilicus,^{77,253,262,270,271} however, a case metastatic to the scalp producing alopecia neoplastica and another case metastatic to the face producing a cellulitis-like picture have been reported.^{30,272} Epidermotropic metastases to the lower abdominal wall, mimicking Bowen's disease, have been reported from a squamous cell carcinoma of the cervix/vagina.²⁷³ Endometrial tumors are adenocarcinomas²⁶¹ or, very rarely, a mixed müllerian tumor,²⁷⁴ whereas those from the cervix may be squamous cell carcinomas,^{258,268} adenosquamous carcinomas,^{21,23} or, rarely, neuroendocrine in type.^{275,276} In a review of the literature of genital carcinomas with metastases to the umbilicus, Galle recorded 18 of ovarian origin, 12 from the uterine body, 1 squamous cell carcinoma from the cervix, and 2 adenocarcinomas from the *fallopian tube*.²⁵³ There is one report of cutaneous metastases from an adenocarcinoma of the *vulva*.²⁷⁷ Squamous cell carcinoma of the *vagina* rarely causes a cutaneous metastatic deposit.^{278,279} Metastasis to the vulva also occurs (discussed previously).⁸⁹

Skin metastases are an unfavorable prognostic sign in *gestational trophoblastic disease*. They occur only in association with widespread disease.^{280,281} Gluteal metastases²⁸² and a solitary nodule in the scalp²⁸³ have been reported. There have been several cases of placental choriocarcinoma metastasizing to the skin of a neonate.²⁸⁴ The histopathology is usually similar to the primary lesion, with large syncytial trophoblastic cells and much hemorrhage.²⁸³ Chorionic gonadotrophin can be demonstrated using immunoperoxidase techniques.

Thyroid

Cutaneous metastasis of thyroid carcinoma is a rare event,²⁸⁵ Brownstein and Helwig recorded only four cases.⁷² In one autopsy study, cutaneous metastases were noted in 2 of 12 medullary carcinomas and 4 of 12 giant cell carcinomas.²⁸⁶ Rarely, follicular, Hürthle cell, papillary, and spindle cell patterns are encountered.^{15,285,287–295} In a review of 43 patients with skin metastases from thyroid carcinoma, a papillary carcinoma was the most common (41%), followed by follicular (28%), anaplastic (15%), and medullary (15%) carcinomas.⁷⁴ The scalp was the most common site of metastasis.⁷⁴

A skin nodule may be the presenting sign of the disease.¹⁵ An unusual presentation in one case was the development of multiple pulsatile nodules on the face, suggesting Kaposi's sarcoma.²⁹⁶ Carcinoma erysipeloides is another rare clinical presentation.²⁹⁷ A rare case of metastatic Hürthle cell carcinoma presented as ulcerated nodules of the scrotum and chin. Microscopic features included sheets of cells with eosinophilic cytoplasm, large nuclei, and cherry-red nucleoli, associated with cell necrosis and numerous mitoses.²⁹⁸ Long survival has been reported after the development of cutaneous metastases,¹⁵ although the average survival in one series was 19 months.⁷⁴ Immunoperoxidase methods can be used to demonstrate calcitonin in medullary carcinomas^{299,300} and to demonstrate thyroglobulin in papillary, follicular, and some anaplastic tumors.^{288,289,295,301} The cells of metastatic Hürthle cell carcinoma expressed thyroglobulin, cyclin D1, and osteoclast-associated receptor keratin.²⁹⁸

Carcinoid tumors

Cutaneous carcinoid tumors may be derived from the bronchus,^{302–304} stomach,³⁰⁵ small bowel, appendix, and large bowel.^{306–308} The bronchus is the most common primary site. Several cases purporting to be primary cutaneous carcinoids have now been reported,^{306,309–311} they appear to behave in a benign manner.³¹² A cutaneous metastasis from an occult primary lesion must be excluded before accepting a case as a primary carcinoid of the skin.³¹³ Metastases from noncutaneous tumors are usually multiple and on the trunk.³⁰² Solitary,^{303,307} umbilical metastases³¹⁴ and precocious metastases³¹⁵ have been recorded. The carcinoid syndrome may be present.^{316,317} Its cutaneous features include flushing, rosacea, and scleroderma.³¹⁸ Pellagra is a not uncommon cutaneous manifestation of the carcinoid syndrome, although it is not specifically related to the presence of cutaneous metastases.^{318,319}

Histopathology

Carcinoid tumors are composed of solid islands and nests of uniform cells (Fig. 39.12).³¹⁴ Thin collagenous septa extend between the tumor nests. A mucinous stroma was present in one purported case of a primary lesion.³¹⁰ In one case, the cutaneous metastasis mimicked a primary adnexal poroid neoplasm.³²⁰ The cells may be argentaffin positive if the primary lesion is in the small or large intestine. Cutaneous metastases of bronchial carcinoids are often devoid of both argyrophil

Figure 39.12 Metastatic carcinoid of the scalp. A primary lesion was found in the terminal ileum some months later. (H&E)

and argentaffin granules. The cells in carcinoid tumors are positive for neuron-specific enolase, and often chromogranin and synaptophysin as well. The cells are negative for CK5/6, CK7, CK20, and p63.³²⁰ Dense-core granules can be seen in the cytoplasm on electron microscopy.³⁰³

Neuroblastoma

Neuroblastomas are the most common tumors of childhood.^{20,321–326} Whereas cutaneous and subcutaneous metastases are found in only 2.6% of cases of neuroblastoma of all ages, they are found in 32% of neonatal tumors.³²⁶ Cutaneous nodules may be the presenting sign of neonatal neuroblastoma.^{322,327} They characteristically blanch on pressure.^{321,323} The pattern of cutaneous metastases may sometimes resemble that of the 'blueberry muffin baby', which is more usually associated with the congenital rubella syndrome.³²⁴ Coexistence of metastatic neuroblastoma and cutaneous extramedullary hematopoiesis has been reported in a 'blueberry muffin baby'.³²⁸

Histopathology

The findings are typical of neuroblastoma, with small cells with hyperchromatic nuclei and rosette formation.³²⁵ The cells stain for neuron-specific enolase by immunoperoxidase methods.

Paradoxically, stage IV-S disease in neonates, in whom there is remote spread of tumor to the liver, skin, and bone marrow, has a relatively good prognosis.³²¹ The tumor may remit or transform spontaneously into a benign ganglioneuroma. With more aggressive treatment protocols, the prognosis is now better than in some of the earlier series of neonatal neuroblastomas.³²⁶

Melanoma

The skin and subcutaneous tissue are common sites of metastases in melanoma.^{6,329,330} Often, they are the first site to become involved.³³¹ There is great variability in the incidence reported in the literature, which reflects in part the different criteria used for inclusion of cases. Local and in-transit (see later) cutaneous metastases are specifically excluded in some series.^{331,332} Metastases to the skin have been present at autopsy in 10–75% of patients with fatal melanoma.^{333–335} It has been the site of the first metastasis in 6–22% of cases.^{331,332} Late metastases are rare,³³⁶ but as Carlson noted, melanomas with slow tumor doubling times may give rise to late metastases.³³⁷ It has been stated that in nearly 5% of patients, a metastasis is the initial presentation of the disease, and no primary lesion can be found.^{338,339} In the author's experience, it is less than 0.5%. Usually, these individuals present with a lymph node metastasis, but sometimes it is in the skin.³³⁸ A mutational analysis study has shown that melanoma metastases of unknown origin have a genotype resembling that of cutaneous melanoma rather than mucosal melanoma.³⁴⁰ Brownstein and Helwig reported 75 cases of metastatic melanoma in the skin, making melanoma the third most common source of cutaneous metastases.⁷² In a 2005 report, five cases of completely regressed primary cutaneous melanomas with nodal and/or visceral metastases were reviewed.³⁴¹

Recently, DNA microarray technology has been used to study gene changes in melanoma cells in cutaneous metastases. There is significant upregulation of several mitogen-activated protein kinase genes in melanoma metastases.³⁴²

A distinct pattern of cutaneous metastasis that is almost unique to melanoma is the development of multiple small nodular deposits, often on a limb, between the site of the primary lesion and the regional lymph nodes.³⁴³ These in-transit metastases probably originate from cells trapped in lymphatics.³⁴⁴ The nodules are bluish, black, or pink in color,³⁴⁵ and they are small and painless. Larger lesions may ulcerate.

Rare clinical presentations have included inflammatory metastases,^{61,345} a pattern resembling Kaposi-like angiodermatitis due to lymphatic spread,³⁴⁶ a hematoma-like lesion,³⁴⁷ a pedunculated tumor,³⁴⁸ a zosteriform distribution,^{38,349,350} a miliary pattern,³⁵¹ metastasis to the breast,³⁵² and diffuse melanosis.³⁵³⁻³⁵⁶ Vitiligo is an uncommon finding in metastatic melanoma.³⁵⁷ Hypercalcemia from bone marrow involvement has also been reported.³⁵⁸ Although widespread cutaneous metastases are usually a poor prognostic sign, some patients with in-transit metastases localized to a limb can survive for many years. In one study, a positron emission tomography scan had low sensitivity in detecting metastases.³⁵⁹

Long-term complete remission of cutaneous melanoma metastases has been reported in a patient using a folk remedy consisting of the ingestion and application of the plant *Thymus vulgaris* (thyme).³⁶⁰ Topical imiquimod has also been used with success in one case.³⁶¹ The use of anti-tumor necrosis factor therapies may lead to reactivation of latent melanoma metastases.³⁶²

Histopathology

There is usually no difficulty in diagnosing cutaneous metastatic deposits, although the rare signet-ring cell melanoma may cause problems.³⁶³ They differ in many instances from a primary lesion by the absence of junctional activity and an inflammatory infiltrate.³⁶⁴ Occasionally, lymphatic or vascular permeation is present.³⁶⁵ Angiotropism may be a clue to the diagnosis of an epidermotropic metastatic melanoma.³⁶⁶ Invasion between collagen bundles in the reticular dermis or into fat lobules of the subcutis, accompanied by incorporation of host stroma islands into the tumor bulk, is associated with a poor prognosis.^{367,368}

Uncommonly, cutaneous metastases are epidermotropic with nests of tumor cells in the junctional zone and within the epidermis.^{329,369-372} The criteria originally suggested for an epidermotropic metastasis³⁶⁹ are no longer regarded as diagnostic (see p. 888).

The immunophenotype of metastatic melanomas usually differs from that of primary tumors. The expression of Ki-67 and mutant p53 protein is usually higher in metastatic tumors than in primary lesions, and CD117 is usually lost in metastatic lesions (except from an ocular primary) but present in cutaneous primary lesions.³⁷³ If melanin pigment is absent from the deposit, the diagnosis can be confirmed by immunoperoxidase studies for S100 protein, melan-A, or HMB-45. The occasional finding of S100 protein in metastases of mammary carcinoma has already been mentioned. Loss of S100 protein staining, or all three markers, has been recorded in metastatic melanoma.^{374,375}

Fluorescence *in situ* hybridization analysis has been used to distinguish metastatic tumors arising from uveal primaries from those originating in skin. In one study, monosomy 3 was detected in 56% of metastatic uveal melanomas but in none of the cases of metastatic cutaneous melanomas.³⁷⁶

Miscellaneous tumors

Rare primary lesions that have been known to metastasize to the skin include an adenoid cystic carcinoma, an acinic cell carcinoma, a myoepithelial carcinoma, and an adenocarcinoma of the salivary gland,³⁷⁷⁻³⁸² an adenoid cystic carcinoma of the lacrimal gland,³⁸³ an ameloblastoma,³⁸⁴ a thymoma,³⁸⁵ an adrenal carcinoma,^{386,387} a pheochromocytoma,³⁸⁸ and carcinomas of the hypopharynx,³⁸⁹ nasopharynx,^{31,390,391} and larynx.³⁹²⁻³⁹⁶ Medulloblastomas,^{397,398} hemangiopericytoma,³⁹⁹ and other tumors, particularly glioblastomas, rarely metastasize to the skin,^{400,401} when they do so, it is usually to the scalp.^{402,403} The author has seen a retinoblastoma metastatic to the skin.

Squamous cell carcinomas of the skin may occasionally metastasize to other cutaneous sites.^{39,40,43,404} Rarely, it is zosteriform in type.⁴⁰⁵ Metastasis from skin cancer in organ transplant recipients has a poor prognosis, particularly if the initial metastasis is distant rather than regional or in-transit.⁴⁰⁶

Brownstein and Helwig reported 19 metastatic sarcomas in their 724 cases of cutaneous metastases.⁷² A footnote in the article states that this figure 'includes leiomyosarcoma, rhabdomyosarcoma, fibrosarcoma, chondrosarcoma, Ewing's sarcoma, osteogenic sarcoma, and undifferentiated sarcomas'.⁷² Leiomyosarcomas of the uterus,^{274,407} small intestine,⁴⁰⁸ mesentery,⁴⁰⁹ and colon metastatic to the skin have been recorded, as have rhabdomyosarcomas^{20,410-412} and fibrosarcoma and malignant fibrous histiocytoma of soft tissues and bone,^{21,413,414} a giant cell tumor of bone,⁴¹⁵ Hodgkin's disease,⁴¹⁶ Ewing's sarcoma,^{20,417} a chondroblastoma,⁴¹⁸ several cases of chondrosarcoma,⁴¹⁹⁻⁴²² a mesenchymal chondrosarcoma of soft tissue origin,⁴²³ a metaplastic breast carcinoma with chondrosarcomatous features,¹⁴⁶ an osteogenic sarcoma (osteosarcoma),⁴²⁴⁻⁴²⁹ a paraganglioma,⁴³⁰ and an angiosarcoma of the aorta (Fig. 39.13)⁴³¹ and heart.⁴³² Mesotheliomas may rarely metastasize to the skin.^{433,434} Several cases of chordoma metastatic to the skin have been reported;⁴³⁵⁻⁴³⁸ direct extension to the skin is more common.^{439,440} We have also seen several cases of metastatic synovial sarcoma (Fig. 39.14).

Figure 39.13 Metastatic angiosarcoma from primary in the abdominal aorta. (A) A papule on the right shin shows this tumor embolus, which proved to be factor VIII⁺. (H&E) (B) A nodular lesion from the left posterior calf shows poorly formed vascular spaces lined by atypical cells, with necrosis and mitotic activity. These cells are strongly positive for CD31. (Immunohistochemistry, CD31 stain)

Figure 39.14 Metastatic synovial sarcoma. This lesion shows poorly differentiated epithelial cells surrounding sweat glands. (H&E)

Figure 39.15 Atrial myxoma embolus. This biopsy is from one of a number of lesions on the hands, mimicking the clinical appearance of papular–purpuric ‘gloves and socks’ syndrome. **(A)** The embolus shows a distinctly mucinous appearance. (H&E) **(B)** The appearance of the same vessel with a mucin stain. (Alcian blue)

Figure 39.16 (A) Atrial myxoma from another case, in a deep dermal vessel of the finger. (B) Loose myxoid tissue is present in the lumen of a small artery. (H&E)

Finally, atrial myxomas may embolize to the skin, producing a varied clinical appearance.^{441,442} The editor is aware of one case with skin lesions mimicking those of the papular-purpuric ‘gloves and socks’ syndrome (**Fig. 39.15**). The tumor emboli, which have a characteristic myxomatous appearance, do not usually extend beyond the vessel wall (**Fig. 39.16**).⁴⁴³

INTRODUCTION

This chapter includes diseases with an infiltrate in the dermis and/or the subcutaneous tissues of cells, other than lymphocytes, derived from the bone marrow or lymphoid tissues; it specifically covers those conditions in which the cutaneous infiltrate is composed predominantly of one cell type.

The various conditions are discussed by cell type. For completeness, mention is made of those conditions fulfilling the definition of 'cutaneous infiltrates' but discussed in other chapters. Special histochemical methods and immunoperoxidase techniques using monoclonal antibodies may be required to characterize fully the particular cell that constitutes the cutaneous infiltrate.

NEUTROPHIL INFILTRATES

Infiltration of the skin by neutrophils is common to numerous diseases of the skin. In most instances, the infiltrate is localized to the dermis, although involvement of the epidermis or the subcutaneous fat may occur in various conditions.

Neutrophils

Neutrophils (neutrophil polymorphonuclear leukocytes) measure 10–12 μm in diameter in tissue sections. They have two to five distinct nuclear lobes, and their cytoplasm contains two distinct types of granules. The larger ones are azurophilic and constitute approximately 25% of the granules in the cytoplasm. They contain myeloperoxidase, bactericidal substrates, cationic proteins, acid hydrolases, and elastase.¹ The smaller granules contain lactoferrin, lysozyme, collagenase, and alkaline phosphatase.¹ These enzymes contribute to the neutrophils' vital role in the defense against invading microorganisms.

Neutrophils are produced in the bone marrow; their maturation from myeloblasts through various intermediate stages takes approximately 7–10 days. Their production and maturation is under the influence of a specific glycoprotein known as granulocyte colony-stimulating factor.^{2,3} Mature neutrophils are released into the circulation, where they spend approximately 7 hours before entering the tissues. Chemotactic substances guide neutrophils to the site of the infective process or another stimulus. They remain functional in the tissues for 1 or 2 days. Their demise is poorly understood: they can be phagocytosed by macrophages in the tissues or spleen; some appear to be excreted from mucosal surfaces.¹

The prime function of neutrophils is phagocytosis and the release of the various enzymes stored in the cytoplasmic granules (discussed previously). An unwanted effect is tissue damage caused by some of these enzymes, particularly collagenase and elastase. Although the part played by neutrophils in the phagocytosis and elimination of organisms, immune complexes, and damaged tissue is well understood, their role in dermatoses such as psoriasis, dermatitis herpetiformis, and the neutrophilic dermatoses is not.

Diseases with neutrophilic infiltrates

All of the conditions characterized by neutrophilic infiltrates in the skin have been discussed in other chapters with the exceptions of Still's disease and congenital and erosive vesicular dermatosis, both of which may have numerous neutrophils in the inflammatory infiltrate.^{4,5} The various neutrophilic diseases were reviewed in 2006.⁶ They are summarized in [Table 40.1](#).

EOSINOPHIL INFILTRATES

Eosinophils are readily identified in tissues, but their role in the pathogenesis of the various cutaneous diseases in which they are found has been obscure until comparatively recently.⁷ It is now known that they are the effector cells for killing helminths and also for causing tissue damage in hypersensitivity diseases.⁷ Eosinophils have also been linked to several inflammatory diseases of the skin associated with edema.^{8–10} They appear to have a role in the downregulation of the inflammation associated with hypersensitivity reactions of immediate type.⁷ Eosinophils also possess phagocytic activity, but less than that of neutrophils.⁷

Eosinophils

Eosinophils are polymorphonuclear leukocytes with a bilobed or trilobed nucleus and cytoplasm that contains approximately 20 eosinophilic-staining granules.¹¹ Ultrastructurally, these granules have an electron-dense core and a relatively radiolucent matrix.¹²

The granular core is the site of production of major basic protein, whereas the other granule proteins (eosinophil cationic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase) are found in the matrix.⁸ The granule proteins are potent toxins, some of which (major basic protein and eosinophil cationic protein) can directly kill metazoal parasites coated with IgE. Eosinophil cationic protein can also cause local tissue damage when it is released.¹³ Major basic protein can cause histamine release from basophils, and most of the granule proteins can induce a wheal-and-flare reaction.⁸ Major basic protein can be detected in the tissues in atopic dermatitis¹⁴ and in some cases of urticaria,¹² even in the absence of significant tissue eosinophilia.⁸ This has important pathogenetic implications for these two diseases.

Other substances produced by the eosinophil include Charcot-Leyden crystal protein, which has lysophospholipase activity; arylsulphatase; leukotriene C_4 ; and platelet-activating factor.⁸ Thromboembolic disorders are more common in patients with the hypereosinophilic syndrome than in other people, presumably as a consequence of enhanced production of platelet-activating factor.¹⁵

Eosinophils originate in the bone marrow, where they spend 3–6 days before being released into the circulation.¹¹ Several factors, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-3 (IL-3), and IL-5, stimulate the production of eosinophils.^{16,17} They are in the blood for a short time and then enter the tissues.¹¹ Only a small proportion of the total number of eosinophils are circulating at any time. Eosinophils appear to go through a late differentiation stage after they have entered the bloodstream.^{15,18} Some eosinophils develop low-density cytoplasm ('hypodense eosinophils') that corresponds with activation of the cell.^{15,18} Chemotaxis for eosinophils is mediated by GM-CSF, IL-5, leukotriene B_4 , platelet-activating factor, and complement fraction 5.¹⁶ Of particular importance is the role of IL-5, which has selective specificity for eosinophils.^{16,17,19} The gene for IL-5 is located at 5q31.1.¹⁷ The selectivity of the eosinophil response to a particular stimulus is due to the receptor profile expressed by eosinophils, which is predominantly the CCR3 receptor.¹⁷ Genetic mutations involving the platelet-derived growth factor receptor genes have been pathogenetically linked to clonal eosinophilia.²⁰

Diseases with conspicuous eosinophils

Eosinophils are a conspicuous component of the inflammatory cell infiltrate in a number of inflammatory and neoplastic disorders. They are listed in [Table 40.2](#).

The distribution of the eosinophils within the skin may be characteristic. This aspect is covered in the discussion of the various entities in other sections of the book. One pattern of distribution of

Table 40.1 Cutaneous diseases with neutrophilic infiltrates

Epidermal neutrophilic infiltrates	Neutrophilic dermatoses
Impetigo	Periodic fever syndromes
Toxic shock syndrome	Sweet's syndrome
Dermatophytoses	Pustular vasculitis of the hands
Chromomycosis	Bowel-associated dermatosis–arthritis syndrome
Sporotrichosis	Rheumatoid neutrophilic dermatosis
Milker's nodule	Acute generalized pustulosis
Orf	Behçet's syndrome
Yaws	Pyoderma gangrenosum
Subcorneal pustular dermatosis	Acute vasculitides
Acute generalized exanthematous pustulosis	Hypersensitivity vasculitis and variants
Pustular psoriasis	Septic vasculitis
Psoriasis	Erythema elevatum diutinum
Reiter's syndrome	Granuloma faciale
Palmoplantar pustulosis	Polyarteritis nodosa
Pustular eruption of ulcerative colitis	Subepidermal blistering diseases
Infantile acropustulosis	Dermatitis herpetiformis
Erythema neonatorum toxicum	Bullous systemic lupus erythematosus
Transient neonatal pustular melanosis	Cicatricial pemphigoid
Pemphigus foliaceus	Ocular cicatricial pemphigoid
IgA pemphigus	Localized pemphigoid
Miliaria pustulosa	Linear IgA bullous dermatosis
Acute generalized pustulosis	Epidermolysis bullosa acquisita
Glucagonoma syndrome	Deep lamina lucida pemphigoid
Halogenodermas	Folliculitides
Verruciform xanthoma	Bacterial and fungal folliculitis
Adult T cell leukemia/lymphoma	Secondary syphilis
Dermal neutrophilic infiltrates	Perforating folliculitis
Infections and infestations	Miscellaneous conditions
Ecthyma	Neutrophilic urticaria
Erysipelas	Polymorphic light eruption
Erysipeloid	Cutis laxa (early stage)
Cellulitis	Eruptive xanthoma
Blastomycosis-like pyoderma	Reticulohistiocytoma
Erosive pustular dermatosis of the scalp	Anaplastic large cell lymphoma
<i>Mycobacterium ulcerans</i> infection	Erythropoietic protoporphyria
Other atypical mycobacterial infections	Neutrophilic eccrine hidradenitis
Erythema nodosum leprosum	Familial Mediterranean fever
Chancroid	Congenital erosive and vesicular dermatosis
Granuloma inguinale	Neutrophilic figurate erythema
Kerion	Still's disease
Actinomycosis	Subcutaneous neutrophilic infiltrates
Nocardiosis	Infective panniculitis (causes as for dermal infiltrates; see above); erythema nodosum leprosum
Mycetoma	Factitial panniculitis
Acute cutaneous leishmaniasis	Pustular panniculitis of rheumatoid arthritis
Secondary syphilis	
Bite reactions (fleas, ticks, and fire ants)	α_1 -Antitrypsin deficiency

Table 40.2 Cutaneous diseases with eosinophilic infiltrates
Vesiculobullous diseases
Dermatitis herpetiformis (late lesions)
Bullous pemphigoid
Bullous arthropod bite reaction
Pemphigus vegetans
Pemphigoid gestationis
Eosinophilic spongiosis
Erythema neonatorum toxicum
Disorders of blood vessels
Urticaria
Hypersensitivity vasculitis (some cases)
Eosinophilic vasculitis
Allergic granulomatosis (Churg–Strauss)
Juvenile temporal arteritis
Angiolymphoid hyperplasia with eosinophilia
Kimura’s disease
Infections/infestations
Parasitic infestations
Dermatophytes (uncommon)
Miscellaneous conditions
Hypereosinophilic syndrome
Wells’ syndrome
Eosinophilic annular erythema
Dermatitis cruris
Pachydermatous eosinophilic dermatitis
Incontinentia pigmenti
Allergic contact dermatitis
Drug reactions
Dermal hypersensitivity
Eosinophilic pustular folliculitis
Eosinophilic pustulosis
Eosinophilic panniculitis
Eosinophilic fasciitis
Eosinophilic, polymorphic and pruritic eruption of radiotherapy
Tumors
Langerhans cell histiocytosis
Tumor-like eosinophilic granuloma
Juvenile xanthogranuloma
Eosinophilic variant, lymphomatoid papulosis
Squamous cell carcinoma
Keratoacanthoma
Malignant melanoma (rare)

eosinophils within the dermis – interstitial eosinophils – is characteristic of certain diseases. The term ‘**interstitial eosinophils**’ refers to the presence of eosinophils between collagen bundles in the intervascular dermis. Eosinophils are invariably present in a perivascular location as well. Interstitial eosinophils are characteristic of various parasitic infestations, particularly arthropod bites (p. 776). However, they are also found in certain drug reactions, including the drug

hypersensitivity syndrome²¹ (see Chapter 20); urticaria (p. 230); PUPPP (toxic erythema of pregnancy; p. 256); Wells’ syndrome (see below); the urticarial stage of bullous pemphigoid (p. 169); eosinophilic, polymorphic, and pruritic eruption of radiotherapy (see p. 614); the hypereosinophilic syndrome (p. 1134); and dermal hypersensitivity reaction (see later).

A discussion of Wells’ syndrome, the hypereosinophilic syndrome, pachydermatous eosinophilic dermatitis, dermal hypersensitivity reaction, and eosinophilic pustulosis follows. Mention is made here of the condition known as dermatitis cruris pustulosa et atrophicans.²² It is a frequent but poorly understood tropical skin condition with intraepidermal pustules and a dermal infiltrate of neutrophils and eosinophils forming flame figures.²²

WELLS’ SYNDROME (EOSINOPHILIC CELLULITIS)

Wells’ syndrome (eosinophilic cellulitis)^{23–27} is a disorder of unknown pathogenesis characterized by the tissue reaction pattern known as ‘eosinophilic cellulitis with flame figures’ (see p. 15).

Clinically, there are edematous infiltrated plaques resembling cellulitis, often with blister formation.²⁸ This is followed by the development of slate-gray morphea-like induration that resolves, usually without trace, over 4–8 weeks.^{24,29,30} Recurrent lesions may develop over a period of months to years. A papulonodular form is uncommon.^{31,32} Milder cases have annular or circinate erythematous plaques.

Although the nosologic position of ‘*eosinophilic annular erythema*’ has been controversial,³³ the prevailing opinion, expressed by Rongioletti *et al.* and others, is that it represents a variant of Wells’ syndrome with an annular or figurate clinical pattern.^{34,35}

Subcutaneous nodules are extremely rare.³⁶ Insect bite-like lesions may occur.³⁷ There is a predilection for the extremities and trunk; rarely, the face is involved as a major clinical feature.³⁸ The lesions followed the lines of Blaschko in one case.³⁹

Wells’ syndrome may occur at any age, although onset in childhood is uncommon.^{30,36,40–45} Several cases occurring in the same family have been documented.^{46,47} In one family, the skin lesions were associated with a dysmorphic habitus, learning disability, and elevated plasma IL-5.⁴⁷

Although most cases of Wells’ syndrome are idiopathic, some are associated with arthropod bites, parvovirus B19 infection,⁴⁸ parasitic infestation (e.g., giardiasis and toxocariasis), drug allergy, tetanus vaccine,^{49,50} thiomersal-containing vaccines,⁵¹ or an atopic history.^{24,26,52–56} It has followed varicella infection in a child⁴³ and has been associated with HIV infection,⁵⁷ molluscum contagiosum,⁵⁸ eosinophilic fasciitis,⁵⁹ bronchogenic carcinoma,⁶⁰ ulcerative colitis,⁶¹ the hypereosinophilic syndrome,^{62–64} systemic lupus erythematosus,⁶⁵ and chronic myeloid leukemia.⁶⁶ There were 25 reported cases of drug-induced Wells’ syndrome by 2013; agents have included antibiotics, anticholinergic agents, anesthetics, nonsteroidal anti-inflammatory agents, thyroid medications, chemotherapeutic agents (including 2-chlorodeoxyadenosine in the treatment of hairy cell leukemia),⁶⁷ thimerosal-containing vaccinations, anti-tumor necrosis factor agents (including infliximab),⁶⁸ and thiazide diuretics.⁶⁹ A number of reports have described an association with Churg–Strauss syndrome.^{70–73} The clinical lesions maintain the characteristic features of Wells’ syndrome, and microscopic findings (see later) include flame figures and lack of morphologic or immunofluorescent changes of vasculitis. A number of these cases have been pANCA positive.⁷³

It has been suggested that circulating CD4⁺ CD7[–] T cells play a pivotal role by producing IL-5.^{59,74} Serum and tissue levels of this cytokine appear to correlate with clinical activity.¹⁶

Many cases resolve spontaneously, but systemic corticosteroids are often used to treat this condition. Minocycline and doxycycline have

also been used in isolated cases.⁷⁵ Interferon (IFN)- α was used in a case with a clonal population of T cells producing IL-5.⁵⁹

Histopathology^{23,76,77}

In early lesions of Wells' syndrome, there is dermal edema and massive infiltration of eosinophils, both interstitial and angiocentric. Subepidermal blisters containing eosinophils may form.²⁸ Blisters may also form from spongiotic vesiculation.⁷⁸ After 1 week, scattered histiocytes and characteristic 'flame figures' are found. The flame figures are surrounded, in part, by a palisade of histiocytes and a few multinucleate giant cells. Uncommonly, there are numerous multinucleate giant cells present.⁷⁹

The inflammatory process involves the entire thickness of the dermis and often the subcutis as well. Localization to the subcutis has been reported as eosinophilic panniculitis (see p. 553). Extensive necrotizing granulomas have been reported in the subcutis in this condition.⁴¹ Rarely, the inflammatory infiltrate extends into the fascia and muscle.⁸⁰

The flame figures consist of eosinophil granule major basic protein encrusted on otherwise normal collagen.²⁹ There is no mucopolysaccharide or lipid, but sometimes basophilic fibrillar material may be seen at the periphery of the eosinophilic material (Fig. 40.1). There is

a superficial resemblance to the Splendore–Hoepli phenomenon, which may develop around metazoal parasites in the tissues.

Electron microscopy

Free eosinophil granules are found coating collagen bundles in the flame figures, but the collagen bundles are not damaged.⁷⁷ Numerous intact eosinophils are also present in the adjacent dermis.

Differential diagnosis

The tissue reaction pattern of eosinophilic cellulitis with flame figures may be seen in a number of disparate conditions,^{23,76,81} including arthropod reactions,^{76,82} other parasitic infestations,⁸³ internal cancers,⁸⁴ etanercept injection sites,⁸⁵ dermatophyte infections,²³ bullous pemphigoid,²³ herpes gestationis,²³ allergic eczemas,²³ and eosinophilic ulcer of the oral mucosa.^{86–88} It is uncommon in all of these conditions, except eosinophilic ulcer of the oral mucosa. Atypical CD30⁺ cells have also been reported in the cellular infiltrate in this condition.⁸⁹ This reaction pattern has also been reported in association with eosinophilic folliculitis, as a manifestation of a drug reaction.⁹⁰ The clinical setting and other histopathological features allow the conditions listed previously to be distinguished from Wells' syndrome.

Figure 40.1 Wells' syndrome. (A) A flame figure is shown. (B) There are many eosinophils in the surrounding dermis. (H&E)

In *eosinophilic annular erythema*, in addition to the features seen in Wells' syndrome, there may be basal vacuolar change and some mucin deposition in the dermis.³³

HYPEREOSINOPHILIC SYNDROME

The hypereosinophilic syndrome (OMIM 607685) is a systemic disorder with involvement of one or more organs and persistent hypereosinophilia ($>1.5 \times 10^9/l$) in the absence of any identifiable cause.^{91,92} Work suggests that a *PDGFRA/FIP1L1* fusion gene may be responsible in some cases (see later). It encompasses a spectrum of disorders that includes eosinophilic leukemia and Löffler's syndrome. Eosinophilic leukemia may initially present as a hypereosinophilic syndrome.⁹³ Cardiac involvement, which may be fatal, is quite common; the lungs, skin, liver, and central nervous system may also be involved.

Cutaneous lesions, which take the form of pruritic erythematous, sometimes eczematized papules and nodules or urticaria and angioedema, are present in half of cases.⁹⁴ Urticarial lesions may manifest as typical urticaria but may also be of longer duration, with features resembling cellulitis or eosinophilic cellulitis (Wells' syndrome).^{64,95} Rarely, they are the only manifestation of the syndrome.⁹⁶⁻⁹⁹ Other mucocutaneous presentations include mucosal ulcerations,¹⁰⁰ erythema annulare centrifugum,¹⁰¹ purpuric lesions, skin necrosis,^{102,103} superficial venous thrombophlebitis,¹⁰⁴ thromboangiitis obliterans,¹⁰⁵ erythroderma,¹⁰⁶ and livedo reticularis.¹⁰⁷ Elevated levels of IgE, IL-2, IL-5, IL-10, and soluble IL-2 receptor may be present.¹⁰⁸ Dermal endothelial cells express eotaxin, a chemokine that is a potent chemoattractant for eosinophils.¹⁰⁹

Cases presenting with episodic or transient angioedema and eosinophilia, but without involvement of other organs, are regarded as a separate entity with a benign clinical course.^{30,91,110} Likewise, the syndrome of hyperimmunoglobulinemia-E with recurrent staphylococcal skin infections, defective neutrophil chemotaxis, and peripheral eosinophilia is a distinct entity.¹¹¹⁻¹¹⁵ There are two distinct hypereosinophilic syndromes: the better known one – Job's syndrome (OMIM 147060) – is autosomal dominant and caused by a mutation in the *STAT3* gene located at 4q21; the other one is an autosomal recessive form (OMIM 243700), in which the mutation has not been characterized. Early onset eczematous lesions, often misdiagnosed as atopic dermatitis, and characteristic facies are other manifestations of Job's syndrome.^{113,116} Rituximab, an antibody against CD20, has been used to treat a case.¹¹⁷ The case that presented with nodular eosinophilic infiltration of the skin and immunoglobulin isotype imbalance is probably a separate condition.¹¹⁸

The precise origin of the hypereosinophilic syndrome is unknown, but it appears to involve a dysregulation of IL-3 and IL-5 and/or GM-CSF.²⁰ The *FIP1L1-PDGFR* (F/P) fusion gene has been identified in some patients with hypereosinophilic syndrome.^{119,120} Such cases have overlap features with chronic eosinophilic leukemia. The two genes that fuse are closely associated at gene map locus 4q12. Chronic active Epstein-Barr virus (EBV) infection was found in a recently reported example of hypereosinophilic syndrome; an EBV-infected V β -5.1 T cell clone producing IL-2 was considered responsible in that case.¹²¹ Another case was associated with IgG κ^+ plasma cells and a D816V exon 17 mutation of the *c-KIT* gene in both bone marrow and skin biopsies, indicating a clonal mast cell activation syndrome.¹²²

Mepolizumab, an antibody to IL-5, appears to be a promising targeted therapy for the hypereosinophilic syndrome.²⁰ Systemic corticosteroids are the current mainstay of treatment.¹²³ Infliximab has also been used.¹²⁴

Histopathology¹²⁵

There is a variable superficial and deep, predominantly perivascular, infiltrate of eosinophils, with variable numbers of lymphocytes, plasma

cells, and mast cells.¹²⁶ Dermal edema is present in urticarial lesions. Thrombosis of small vessels in the dermis is a rare finding.¹⁰⁷ The microthrombi often contain eosinophils.¹²³

In the syndrome of recurrent angioedema with eosinophilia, the infiltrate is primarily mononuclear, with only a few eosinophils.¹²⁷ However, with immunofluorescence there is extracellular localization of eosinophil major basic protein.

PACHYDERMATOUS EOSINOPHILIC DERMATITIS

Pachydermatous eosinophilic dermatitis is possibly a variant of the hypereosinophilic syndrome. It is associated with a generalized pruritic papular eruption arising on a pachydermatous base, hypertrophic lesions in the genital area, and peripheral blood eosinophilia.¹²⁸ The reported cases have been predominantly in South African black teenage girls, but a recent report from Croatia describes the condition in a Caucasian female patient.¹²⁹ The latter patient improved with therapy consisting of dapsone, methylprednisolone, and fexofenadine.¹²⁹ The etiology is unknown.

Histopathology

The lesions showed an eosinophil-rich lymphohistiocytic infiltrate and variable fibrosis of the dermis. The infiltrate varied in amount and distribution. Interstitial eosinophils were often present, and there was abundant eosinophil granule major basic protein.¹²⁸

DERMAL HYPERSENSITIVITY REACTION

Dermal hypersensitivity reaction (DHR) is the most controversial concept in dermatopathology because of its inconsistent usage, its variable clinicopathological correlations, its enigmatic nature, and the emotive climate that accompanies the use of the term.^{130,131} LeBoit termed it 'the last refuge of scoundrels'.¹³² Against this background, the authors of this book now believe that after practicing dermatopathology for more than 35 years apiece, and despite unquestioned abuse of the term by some, no other concept/diagnosis appropriately encompasses the pathological findings that occur in some patients in a defined etiological setting. The authors are also aware of the disdain held for *converts* by some persons: 'The impudence of a bawd is as nothing to that of a convert' – George Saville, Lord Halifax (1633–1695). The term used by Kossard and colleagues, **urticarial dermatitis**, comes closest to an appropriate substitute designation for DHR; however, by their own admission, urticarial dermatitis applies only to a subset of patients having DHR.¹³³ Some of the cases reported as papular dermatitis (subacute prurigo, 'itchy red bump' disease) are probably further examples of DHR.^{134,135}

The clinical presentation is variable, but lesions are usually intensely pruritic. There may be persistent urticarial plaques, urticated erythema, or a papular eruption involving the trunk and limbs. The latter presentation is usually symmetrical. Involvement of the face and neck is much less common. It may occur at any age. Lesions persist for months or years. Resolution of the lesions, with subsequent recurrence, is sometimes seen.

Dermal hypersensitivity reaction may be idiopathic or follow well-documented events such as drug ingestion; vaccination; an arthropod or snake bite; infection, particularly of viral type; and an internal malignancy, including lymphoma.^{131,136} One author has seen many cases with a generalized eruption that followed local skin contact with the sap of the papaya or the macadamia nut tree. The generalized rash was not an autoeczematization.

Treatment with mycophenolate mofetil,¹³⁷ or low doses of prednisone combined with either dapsone or hydroxyurea, has been used.¹³⁸

Figure 40.2 (A) Dermal hypersensitivity reaction. (B) There is a tight perivascular infiltrate of lymphocytes and fewer eosinophils than usual. (H&E)

Histopathology

The most common pattern is a superficial and, to a much less extent, deep perivascular infiltrate of lymphocytes admixed with a few eosinophils, combined with many interstitial eosinophils (**Fig. 40.2**). They are sometimes more numerous than in arthropod bite reactions, which can usually be excluded because of the symmetrical nature of the rash or the presence of large plaques. It should be remembered that not every lesion in a bite reaction, particularly scabies, is due to arthropod contact. Some lesions are examples of a hypersensitivity reaction.

Mild urticarial edema and mild epidermal spongiosis, which is usually more diffuse than seen with arthropods, are often present. Epidermal changes of scratching are present in older lesions. A few basal apoptotic keratinocytes are sometimes present.

Another pattern seen in DHR resembles a lymphocytic vasculitis, with a tight perivascular cuff of lymphocytes, with a few admixed eosinophils. Fibrin and red cell extravasation are rarely present, suggesting that the infiltrate may be directed at antigen-processing endothelial cells rather than representing a true vasculitis.¹³⁹ In one recent study of herpetic dermatitis, three cases without viropathic changes but with histopathologic features of a dermal hypersensitivity

reaction (i.e., superficial and deep dermal eosinophilic infiltrates) were confirmed to have varicella-zoster viral infection by polymerase chain reaction (PCR) methodology.¹⁴⁰

EOSINOPHILIC PUSTULOSIS

Eosinophilic pustulosis is an appropriate designation for a spectrum of cases originally reported as eosinophilic pustular folliculitis of infancy (see p. 463).¹⁴¹ Although it was originally regarded as a dermatosis of the scalp, cases with lesions in other sites have been reported. Furthermore, this condition was originally regarded as a follicular process similar to Ofuji's disease, but cases with a predominantly interfollicular infiltrate have since been reported. The papulopustular lesions reported in the genital region appear to belong to this spectrum.¹⁴²

The etiology is unknown. Scabies infection has not been present.

Histopathology

There is a heavy dermal infiltrate of lymphocytes, neutrophils, and numerous eosinophils. By definition, there is no primary folliculitis. There is usually no subepidermal edema, and the infiltrate is more polymorphic than in Wells' syndrome.

PLASMA CELL INFILTRATES

Plasma cells are not usually present in the peripheral blood or normal skin, although they may be found in normal mucous membranes. They are also prevalent in the skin in certain anatomic sites, including the face, posterior neck, axillae, breasts, anogenital region, and pretibial areas. However, they may be a component of the inflammatory infiltrate in a wide range of dermatoses and tumors of the skin.¹⁴³ These conditions are considered after a discussion of the normal plasma cell.

Plasma cells

Plasma cells are terminally differentiated cells that are derived from antigenically stimulated B lymphocytes.¹⁴³ During their life span of 2 or 3 days, they continuously synthesize and secrete antibodies that have specificity for the particular antigen that stimulated the plasma cell precursor to proliferate and differentiate.

Plasma cells have abundant basophilic cytoplasm and an eccentrically placed nucleus with coarse chromatin granules, which are often distributed in a cartwheel pattern. Occasionally, the cytoplasm contains a round eosinophilic inclusion that may displace the nucleus to the periphery or be liberated into the stroma. These Russell bodies, which may measure up to 20 μ m in diameter, result from the accumulation of immunoglobulins and glycoproteins in the cytoplasm.¹⁴⁴ They are periodic acid-Schiff (PAS) positive and diastase resistant. Russell bodies are particularly prominent in the inflammatory infiltrate in rhinoscleroma.

Ultrastructural examination reveals a well-developed rough endoplasmic reticulum with numerous ribosomes. These are involved in the synthesis of a particular immunoglobulin. The endoplasmic reticulum is the site of formation of the Russell bodies. Crystalloid inclusions, iron, and even bacteria have been found in the cytoplasm of plasma cells in various circumstances.¹⁴³

Numerous basophilic extracellular bodies, reminiscent of yeast cells, have been found in the dermis in association with plasma cell infiltrates.¹⁴⁵ These structures, known as plasma cell bodies, may measure up to 5 μ m in diameter and are derived from the cytoplasm of plasma cells.¹⁴⁵

In contrast to B lymphocytes, plasma cells have very small amounts of immunoglobulin on their cell membrane, although it may be demonstrated in the cytoplasm by immunoperoxidase methods. This may

be useful in distinguishing reactive proliferations of plasma cells, which are polyclonal, from plasmacytomas and myelomatous infiltrates, which are monoclonal. Plasma cells stain for CD79a; CD38 is used as a marker in flow cytometry. CD138 is another marker for plasma cells.

Plasma cell hyperplasias

Plasma cells may be a prominent component of the inflammatory infiltrate in a number of dermatoses and neoplastic disorders.¹⁴³ It should be remembered that plasma cells are almost invariably present in any condition involving the lips and other mucous membranes.¹⁴⁶ For some inexplicable reason, they may also be prominent in lesions of the forehead and scalp, particularly in keratoses and skin cancers previously subjected to cryotherapy.¹⁴⁷

Plasma cells are particularly prominent in the inflammatory infiltrate in syphilis (p. 674), granuloma inguinale (p. 664), chancroid (p. 665), yaws (p. 678), rhinoscleroma (p. 666), erythema nodosum leprosum (p. 662), necrobiosis lipoidica (p. 203), the nodular form of primary cutaneous amyloidosis (p. 437), chronic folliculitis (p. 465), Kaposi's sarcoma (p. 1101), and syringocystadenoma papilliferum (p. 944).¹⁴³ They may be prominent at the lower edge of the dermal infiltrate in a subgroup of patients with mycosis fungoides (p. 1176)¹⁴⁸ and at the periphery of the rare entity known as inflammatory pseudotumor. This latter lesion has the low-power appearance of a lymph node with variable central fibrosis, but no sinuses are present.¹⁴⁹⁻¹⁵¹

Plasma cells are a less consistent feature in certain deep fungal infections, cutaneous lupus erythematosus, rosacea, scleroderma, pseudolymphoma, persistent light reactions, drug reactions,¹⁵² and the reaction to certain arthropods.¹⁴⁷ A panniculitis rich in plasma cells may be seen in scleroderma, morphea profunda, dermatomyositis, and Sjögren's syndrome. Rarely, they are present in lichen planus.¹⁵³ Plasma cells are a diagnostic feature of one variant of Castleman's disease (p. 1139). Plasma cells are often present in the stroma of various tumors, such as squamous cell carcinomas and basal cell carcinomas, and malignant melanomas, particularly if ulceration has occurred.

PLASMACYTOMAS AND MULTIPLE MYELOMA

These conditions should probably have been considered in Chapter 41 with the lymphoid infiltrates. To do so would have created certain logistical problems. For this reason, they are again considered in this chapter. Cutaneous plasmacytomas are rare monoclonal proliferations of plasma cells that are usually associated with underlying multiple myeloma, extramedullary (soft tissue) plasmacytomas, or, rarely, plasma cell leukemia.^{154,155} These *secondary cutaneous plasmacytomas* are usually multiple. They may arise by direct spread from an underlying tumor deposit in bone or soft tissue or by metastatic spread via lymphatics or blood vessels.¹⁵⁶ Cutaneous plasmacytomas develop in only a small percentage of cases of multiple myeloma and of extramedullary plasmacytoma.^{154,156-159} Only 20 cases were noted in a series of 2357 patients with the diagnosis of multiple myeloma.¹⁶⁰ They are a poor prognostic sign.^{156,161} Sometimes cutaneous lesions are the presenting sign of multiple myeloma and, rarely, they may antedate the development of the full-blown disease.¹⁶² It has been suggested that IgA- and IgD-producing plasmacytomas are disproportionately represented in the skin.¹⁶³

Primary cutaneous plasmacytomas, which by definition arise without concomitant bone marrow or soft tissue disease, are exceedingly rare.¹⁶⁴⁻¹⁶⁹ They are included in the current World Health Organization (WHO)/European Organization for Research and Treatment of Cancer (EORTC) classification with the B cell lymphomas (see pp. 1172 and 1207). They constitute only 2–4% of all cases of primary extramedullary plasmacytomas.¹⁷⁰ They usually grow slowly

and are solitary; multiple lesions are sometimes present.¹⁷¹⁻¹⁷⁵ The prognosis is not as good as previously thought: visceral metastases and death occur in more than one-third of cases.^{176,177} Transformation of a cutaneous plasmacytoma into a CD30⁺ diffuse large B cell lymphoma has been reported as a consequence of EBV infection.¹⁷⁸ Rarely, a local triggering stimulus may be involved in the development of a primary cutaneous plasmacytoma. One such case involved recurrent herpes simplex virus (HSV-1) infection of the lip with the development of a plasmacytoma at the site after 15 years of recurrent infection.¹⁷⁰ The authors hypothesized that recurrent infection resulted in the toll-like receptor activation and, in turn, IL-6 release producing plasma cell proliferation, transformation, and survival.¹⁷⁰ Cases associated with transplantation and chronic immunosuppression have been reported.^{175,179}

Plasmacytomas are dusky red or violaceous dome-shaped nodules that measure 1–5 cm in diameter. They have a predilection for the trunk, but they may also develop on the extremities and the face.

Multiple myeloma

Multiple myeloma (myelomatosis) is a malignant proliferation of plasma cells that typically involves the bone marrow but may also involve other tissues.¹⁸⁰ It is a disease of older persons; the median age in a large series from the Mayo Clinic was 66 years.¹⁸¹ The median duration of survival was 33 months.¹⁸¹ Myeloma usually presents with bone pain, anemia, renal insufficiency, hypercalcemia, and proteinuria.¹⁸⁰ A monoclonal spike is found in the electrophoretic pattern of the serum, and sometimes of urine, in which Bence-Jones protein may also be detected. Amyloidosis may subsequently develop. Cutaneous manifestations of multiple myeloma include the development of xanthomas; amyloid deposits; nonspecific erythemas; neoplastic plasma cell infiltrates (Fig. 40.3);¹⁸² pyoderma gangrenosum-like lesions; cutaneous infections, including herpes zoster; and hemorrhagic lesions.^{180,183,184} Other diseases can occur following autologous peripheral stem cell transplants and various types of bone marrow transplantation used in the treatment of myelomatosis.¹⁸⁵ Elevated serum IL-16 was found in one patient with multiple myeloma with cutaneous involvement; this is a known feature correlating with poor prognosis in myeloma patients,

Figure 40.3 Multiple myeloma. The cells retain some features of conventional plasma cells, but many of the nuclei do not display the classic 'clock face' chromatin pattern. The cells with high nuclear:cytoplasmic ratios and prominent nucleoli are plasmablasts. (H&E)

Figure 40.4 Plasmacytoma composed of mature plasma cells. (H&E)

in whom IL-16 may have an adverse effect on the regulation of cell proliferation and mobility.¹⁸⁶

Histopathology

Cutaneous plasmacytomas are circumscribed non-encapsulated dense infiltrates of plasma cells, situated usually in the reticular dermis but sometimes involving the subcutis as well. The epidermis is often stretched over the deposit, but ulceration is uncommon. The plasma cells show variable maturation (Fig. 40.4). Russell bodies are often present in lesions with many mature plasma cells. In secondary and rapidly growing primary lesions, there is more variation in the size and the maturation of the plasma cells, with some binucleate cells and scattered mitoses.¹⁸⁷ Rare variants of plasma cell tumors include pleomorphic, blastic, signet-ring, small cell, clear cell, and spindle cell forms.¹⁸⁸ Sometimes the cells are immature and resemble immunoblasts or the cells of a malignant lymphoma. These cases with dedifferentiated cells are now classified as lymphoplasmacytoid lymphomas or immunocytomas.¹⁸⁹ Their monoclonal nature can be confirmed by immunohistochemistry (Fig. 40.5). Occasional plasmacytomas are polyclonal.¹⁹⁰ The specific plasma cell antibody PC-1 and also CD79a can be used for their confirmation.¹⁴³ Plasmacytomas are often negative for CD45 and can be cytokeratin positive, leading to an erroneous interpretation of cancer. The cells do not usually express B-lineage cell surface markers such as L26 (CD20).¹⁷⁷ Cutaneous plasmacytomas express CD117 in a cytoplasmic, or membranous and cytoplasmic, distribution, with varying degrees of staining intensity.¹⁹¹ The methyl green–pyronin stain, in which the cytoplasm of plasma cells stains red, may be used to confirm the cell type in less well-differentiated deposits.¹⁹² The expression of syndecan-1 (CD138) is a sensitive marker for cutaneous plasmacytomas, independent of cytological differentiation.^{160,193} It is not always expressed in myeloma deposits.¹⁹⁴

There is one report of needle-like crystalloid inclusions, possibly representing phagocytosed protein, in the cytoplasm of macrophages that were admixed with the plasma cells.¹⁹⁵ Further reports document patients with myeloma with crystalline deposits in the skin but without accompanying plasma cells.^{196,197} The term **crystal-storing histiocytosis** has been used for these cases.¹⁹⁷ Amyloid is another uncommon finding in the cutaneous lesions.

Electron microscopy

The immature plasma cells found in some rapidly growing plasmacytomas and cutaneous deposits of multiple myeloma have less abundant rough endoplasmic reticulum than do mature cells.¹⁷⁶

Figure 40.5 Plasmacytoma. Immunostaining for κ light chains: (A) is negative, whereas staining for λ light chains (B) is strongly positive in this case. (Light chain staining via *in situ* hybridization)

Cutaneous disorders associated with paraproteinemias

A heterogeneous group of cutaneous diseases have been associated with multiple myeloma or with a monoclonal gammopathy. These include necrobiotic xanthogranuloma, xanthoma disseminatum, generalized plane xanthomas, lichen myxedematosus and scleromyxedema, scleredema, erythema elevatum diutinum, subcorneal pustular dermatosis, pyoderma gangrenosum, dermatitis herpetiformis, a subepidermal bullous dermatosis,¹⁹⁸ acquired angioedema, angioimmunoblastic lymphadenopathy, cutaneous T-cell lymphoma, mycosis fungoides, and the Sézary syndrome.¹⁹⁹

A monoclonal protein is present in approximately 75% of cases of the POEMS syndrome (*poly*neuropathy, *org*anomegaly, *end*ocrinopathy, *M*-protein, and skin lesions).^{200–203} It is also known as Crow–Fukase syndrome. The cutaneous lesions include hyperpigmentation, hypertrichosis, and skin thickening.²⁰⁴ Glomeruloid hemangiomas also occur (see p. 1085). Xanthoma cells have been described in the hyperpigmented patches of one patient.²⁰⁵ Increased serum levels of vascular

endothelial growth factor have been reported in this syndrome.²⁰⁶ Increased serum levels of IL-6 and also human herpesvirus type 8 (HHV-8) infection have been reported, as also occurs in Castleman's disease (see later).²⁰⁷ Improvement of the skin lesions in POEMS syndrome has been reported after UVA-1 phototherapy.²⁰⁸

In Schnitzler's syndrome, there is chronic urticaria associated with macroglobulinemia, but criteria for the diagnosis of Waldenström's disease (discussed next) are lacking.²⁰⁹

WALDENSTRÖM'S MACROGLOBULINEMIA

Waldenström's macroglobulinemia is a lymphoproliferative disorder of the elderly in which IgM-producing lymphoplasmacytoid cells proliferate in the bone marrow and/or lymph nodes and spleen.^{210,211} It is now regarded as a lymphoma of small B lymphocytes, plasma cells, and plasmacytoid cells (see p. 1206). The cell of origin of Waldenström's macroglobulinemia is believed to be a memory B cell that has undergone somatic mutation. The principal cytogenetic abnormality is del(6q), typically in the region 6q23–24.3, present in up to 50% of cases.²¹² Clinical features include weight loss, weakness, anemia, and a bleeding diathesis. Transition to marginal zone B cell lymphoma has been described.²¹³

Cutaneous manifestations are usually nonspecific and result from hyperviscosity of the blood and the bleeding tendency. They include purpura, discoloration of the fingertips and toes, leg ulcers,²¹⁴ urticaria, bullae, and angioedema.^{215,216} Specific skin lesions are quite rare. They take the form of translucent papules composed of deposits of monoclonal IgM (macroglobulinosis cutis or 'storage papules'),^{217,218} and of violaceous plaques, nodules, or macular lesions on the face, trunk, or proximal parts of the extremities; the plaques, nodules, and macules are composed of lymphoplasmacytoid cells.^{163,211,217,219,220} The cutaneous lesions usually develop later in the course of the disease, although they may be the presenting feature.²¹⁹

Histopathology²¹⁰

The rare translucent papules consist of eosinophilic hyaline deposits filling the papillary and upper reticular dermis. Artifactual clefts may be present.²¹⁷ Sometimes the material encases the hair follicles; it may undergo transepithelial elimination. The hyaline deposits are strongly PAS positive, but they are negative with stains for amyloid. They are monoclonal for IgM, using immunofluorescent techniques, and also stain for light chains.²²¹

The plaques and tumors are composed of a dense infiltrate of lymphoplasmacytoid cells in the reticular dermis.²¹⁰ Occasional binucleate cells and mitotic figures are present. Some of the cells contain intranuclear inclusions (Fig. 40.6) that are PAS positive.¹⁶³ Hyaline material, which is monoclonal IgM, is sometimes present between the cells (Fig. 40.7). IgM has also been reported along the basement membrane zone of both lesional and nonlesional skin.^{222,223} Sometimes a leukocytoclastic vasculitis is also present.²¹⁶

Electron microscopy

The hyaline deposits are composed of granular material that is electron dense. Fibrils are usually absent,^{217,218} although they were present in one case.²²⁴ The lymphoplasmacytoid cells in the infiltrative lesions have abundant ribosomes and sometimes intranuclear inclusions composed of granular material.

Differential diagnosis

Macroglobulinosis cutis (storage papules) can be confused with amyloidosis or colloid milium, but the amorphous material fails to stain as amyloid or colloid and is found to contain IgM. Despite some variation in the ultrastructural descriptions of these lesions, the material clearly differs from the straight, nonbranching filaments, 6 or 7 nm in

Figure 40.6 Macroglobulinemia of Waldenström. With oil immersion, an intranuclear inclusion (Dutcher body) can be seen in a plasma cell (arrow). (H&E)

Figure 40.7 Macroglobulinemia of Waldenström. There is a diffuse lymphocytic and plasmacytic dermal infiltrate. Hyaline material is present between cell aggregates and around adnexa, representing monoclonal IgM. (H&E)

diameter, that characterize amyloid. It also differs from juvenile colloid milium, which is composed of wavy filaments 8–10 nm in diameter. There may be a greater resemblance to adult colloid milium, but the latter usually shows evidence of derivation from solar elastotic fibers.

CUTANEOUS AND SYSTEMIC PLASMACYTOSIS

'Systemic plasmacytosis' has been applied in cases with multiple brownish plaques, asymptomatic generalized lymphadenopathy, and polyclonal hypergammaglobulinemia.^{225–227} There is one report of a patient with systemic plasmacytosis later developing a nodal T-cell lymphoma.²²⁸ The term 'cutaneous plasmacytosis' has been used for the skin lesions when lymphadenopathy is absent.^{226,229–233} This distinction is somewhat artificial because some cases of cutaneous plasmacytosis have subsequently developed systemic disease.^{234,235} The term 'cutaneous and systemic plasmacytosis' is now being used for this

entity, reflecting the variable systemic involvement that may accompany cutaneous disease.²³⁶

Cutaneous plasmacytosis is a rare skin disorder, most common in Japan, characterized by multiple dark-brown papules and plaques, located predominantly on the trunk.^{237,238} There is often a polyclonal hypergammaglobulinemia. Some cases are associated with an underlying malignancy.²³⁷ HHV-8 was not detected in one study.²³⁹ A case has been reported in a child.²⁴⁰

IL-6, a major plasma cell growth factor, has been increased in the serum in some cases.²⁴¹

Histopathology

Cutaneous plasmacytosis is characterized by moderately dense, superficial and deep, perivascular infiltrates in the dermis, composed of mature plasma cells and a small number of lymphocytes.²²⁵ Sometimes lymphoid aggregates and a few multinucleated giant cells are present. A few interstitial histiocytes are usually seen.²³⁹ There is some resemblance to the lesions of secondary syphilis. There is no light chain restriction.²³⁹

Differential diagnosis

There may be a broad spectrum of clinicopathologic features in this condition, with elements resembling cutaneous marginal zone lymphoma and Castleman's disease.²⁴² In fact, there has been some controversy regarding the possible relationship of cutaneous and systemic plasmacytosis to Castleman's disease (see later). This is highlighted by a case in which clinical features (multiple plaques and nodules involving the face, without systemic symptoms) and laboratory findings (polyclonal hyperglobulinemia) supported cutaneous and systemic plasmacytosis but skin biopsy findings (lymphoid follicles, 'onion ring' appearance of the mantle zone, capillaries penetrating the germinal centers in radial arrangement, and proliferation of hyalinized vessels in the dermis with an infiltrate of lymphocytes and mature plasma cells) were typical of the mixed type of Castleman's disease.²⁴³

PLASMACYTOSIS MUCOSAE (INCLUDING ZOOON'S BALANITIS/VULVITIS)

An almost endless variety of terms have been used for comparable lesions involving the penis (plasma cell erythroplasia, balanitis circumscripta plasmacellularis, Zoon's balanitis), vulva (vulvitis circumscripta plasmacellularis, Zoon's vulvitis), lips (plasma cell cheilitis),²⁴⁴ and other mucosal surfaces (plasma cell orificial mucositis,²⁴⁵⁻²⁴⁷ atypical gingivostomatitis,²⁴⁸ plasmacytosis circumorificialis²⁴⁹). The term 'plasmacytosis mucosae' has the advantages of relative simplicity, of applying to all mucosal sites, and of indicating that plasma cells are an important component of the inflammatory infiltrate. Both oral and genital involvement have been reported in the same patient.²⁵⁰

Plasmacytosis mucosae is a rare disorder that most frequently involves the glans penis and/or prepuce of older uncircumcised men (Zoon's balanitis).^{249,251-256} It has also been reported in circumcised males.²⁵⁷ Vulval lesions (Zoon's vulvitis), which usually involve adults, are exceedingly rare, with fewer than 50 cases reported.^{251,258-263} It may be the cause of intractable vulvar pruritus.²⁶⁴ Genital lesions usually take the form of a solitary, asymptomatic, sharply defined red-brown glistening patch measuring 1–3 cm in diameter. Occasionally, several lesions may be present. A tumorous variant has also been described (plasmoacanthoma).²⁴⁵ A plasmoacanthoma in the perianal region has been reported in a patient with intertriginous plasmacytosis.²⁶⁵

The lesions are usually resistant to treatment, although circumcision has resulted in the disappearance of some lesions of the glans.²⁵⁴ The etiology is unknown,²⁵⁸ although herpes simplex antigen has been detected in rare cases,²⁶⁶ and one case has been associated with

autoimmune polyglandular endocrine failure, raising the possibility of autoimmunity in the etiology.²⁶⁷ It is probably a chronic, reactive, principally irritant mucositis.²⁶⁸

As mentioned previously, circumcision is the usual treatment for Zoon's balanitis, but success with topical steroids and laser has been reported.²⁶⁹ Tacrolimus (topical) has also been used with a successful outcome.²⁷⁰⁻²⁷³ Two cases of Zoon's balanitis have been treated successfully with pimecrolimus 1% cream.²⁷⁴

Histopathology²⁵¹

There is a dense, often band-like infiltrate of inflammatory cells in the upper dermis, which may extend to the level of the mid-reticular dermis. The infiltrate is composed predominantly of polyclonal plasma cells,^{245,246,255} sometimes containing Russell bodies. The number of plasma cells seems to vary with the stage of the disease; sometimes they are sparse.²⁷⁵ There may also be lymphocytes, mast cells, occasional eosinophils, and even neutrophils in the infiltrate. Neutrophils are more common beneath the epidermis.²⁵⁶ The presence of lymphoid follicles is a rare event.

Blood vessels are prominent, with an increase in number and some dilatation. There is often extravasation of erythrocytes. Deposits of hemosiderin may be present, although they have not been a feature of nongenital lesions. With time, there is some fibrosis. In a study of 45 cases, Weyers and colleagues found that fibrosis, extravasated erythrocytes, siderophages, atrophy of the epidermis, and a dense infiltrate with predominance of plasma cells seemed to reflect more advanced lesions.²⁵⁶

The overlying epidermis is usually attenuated; frank ulceration occurs in only a minority of cases (Fig. 40.8). In early lesions, it may be of normal thickness with focal parakeratosis. The epidermis is often mildly edematous (spongiosis) and may contain a few inflammatory cells and erythrocytes. So-called 'lozenge-shaped' or diamond-shaped keratinocytes may be identified. Mucinous metaplasia has been reported in Zoon's vulvitis.²⁷⁶

Sometimes, cases diagnosed initially as Zoon's balanitis turn out to be examples of other diseases, such as psoriasis, lichen planus, or allergic contact dermatitis.²⁵⁶

In *plasmoacanthoma*, there is an acanthotic and hyperkeratotic epidermis overlying a polypoid tumor composed of a dense dermal infiltrate of mature plasma cells.²⁶⁵ Russell bodies are also present.

Electron microscopy²⁴⁹

The plasma cells in the infiltrate contain considerable rough endoplasmic reticulum. Phagolysosomes may be present. There are also macrophages containing siderosomes.

CASTLEMAN'S DISEASE

Castleman's disease (giant lymph node hyperplasia) is a distinctive lymphoid hyperplasia that occurs predominantly in the mediastinum of young to middle-aged persons.²⁷⁷ There are two *histological* variants, a common hyaline vascular type and a less common plasma cell type, which often has systemic manifestations. A mixed variant, the intermediate type, also occurs. In addition, two *clinical* types have been described: localized disease and multicentric Castleman's disease.²⁷⁸

Cutaneous manifestations of multicentric Castleman's disease are usually nonspecific. They include plane xanthomas and vasculitis.²⁷⁹ Erythroderma has been described.²⁸⁰ Cutaneous involvement is rare, with only a few cases reported.^{277,281,282} Cutaneous plasmacytosis has also been reported in patients with multicentric Castleman's disease.^{207,283} An association with POEMS syndrome (discussed previously) has been recorded,²⁸⁴ which may represent a variant of Castleman's disease. Castleman's disease is also one of the conditions associated with paraneoplastic pemphigus.^{285,286}

Figure 40.8 Zoon's balanitis. (A) Ulceration is present. (B) There is increased vascularity and many plasma cells. (C) Plasma cells are present beneath a mildly attenuated epidermis. (H&E)

Figure 40.9 Castleman's disease. Within a lymph node, a lymphoid follicle with an atrophic germinal center can be identified. Small lymphocytes are observed in the mantle zone, and a permeating, hyalinized vessel is also evident. (H&E)

A variant of the hyaline vascular type with lesions confined to the subcutis and skeletal muscle has been reported.²⁸⁷ The cases were not associated with POEMS syndrome, HHV-8, or monoclonal rearrangements of IgH.²⁸⁷ The lesions ranged in size from 4 to 6 cm in diameter and had a yellow-brown to red-brown color.²⁸⁷

The pathogenesis is unknown, but elevated levels of IL-6, a cytokine necessary for the maturation of B lymphocytes into plasma cells, are often present. IL-6 also stimulates endothelial hyperplasia.²⁸⁸ HHV-8 has been implicated in the etiology of multicentric Castleman's disease.^{289,290} The cells are usually polyclonal in origin, but rare cases with a monoclonal population of cells have been noted.²⁷⁸ A sarcoma of presumptive follicular dendritic cell origin has been reported in a case of hyaline-vascular Castleman's disease of the skin and subcutis;²⁹¹ in another case, a clonal cytogenetic aberration involving the long arm of chromosome 12, with rearrangement of the high-mobility group protein I-C (*HMGIC*) gene, resulted in a clonal proliferation of follicular dendritic cells.²⁹² One report suggested that HIV-positive multicentric Castleman's disease may arise from extrafollicular B cells.²⁹³

Localized Castleman's disease is generally curable by surgical excision, whereas the multicentric variant often requires systemic therapy and has a poorer prognosis.²⁷⁸

Histopathology

Cutaneous cases are so rare that few histological reports exist. Reported cases have had a circumscribed nodule composed of ill-defined lymphoid follicles with a mantle of small lymphocytes giving an 'onion-skin' appearance. These mantles were traversed by hyalinized capillary-sized vessels. The interfollicular zones were composed of lymphocytes, and plasma cells of polyclonal type (Fig. 40.9).²⁷⁷ Another case was described as showing a deep dermal and subcutaneous nodular infiltrate of plasmacytoid cells without atypia and also an increased vascular proliferation.²⁸²

Mild to marked follicular dendritic cell dysplasia may be present in cases localized to the subcutis and muscle.²⁸⁷ The cells are highlighted by CD21 and CD35 stains.

Differential diagnosis

Cutaneous lesions of Castleman's disease may resemble lymphocytoma cutis, which also shows lymphoid follicles and small vessel

proliferation. However, the latter lesion lacks atrophic germinal centers, the ‘onion-skin’ layering of mantle lymphocytes, and the hyalinized appearance of the vessels. Angiolymphoid hyperplasia with eosinophils most commonly (but not exclusively) involves the ear or periauricular tissues; usually lacks well-formed lymphoid follicles; contains numerous eosinophils; and possesses vessels that are not hyalinized but feature protuberant, ‘histiocytoid’ endothelial cells.^{277,294} Kimura’s disease shows hyperplastic lymphoid follicles but lacks the hyalinized vessels. Castleman’s disease lacks the atypical forms or monotony seen in lymphomas or angioimmunoblastic lymphadenopathy. However, there are rare examples of marginal zone B cell lymphoma with prominent plasma cell differentiation that resemble the plasma cell variant of Castleman’s disease, complete with atrophic germinal centers; one of these cases showed monotypic κ light chain restriction.²⁹⁵ Despite the prominence of plasma cells in many cases of Castleman’s disease, their usual polyclonality, combined with the presence of lymphoid follicles, helps distinguish this condition from cutaneous involvement by myeloma or plasmacytoma. Examples of cutaneous Castleman’s disease with large numbers of IgG4⁺ cells could also be confused with IgG4-related disease, a newly described fibroinflammatory condition that also uncommonly involves the skin (discussed next).²⁹⁶ IgG4-related disease can produce erythematous cutaneous plaques and nodules. Microscopically, it is associated with nodular, deep dermal/subcutaneous infiltrates of lymphocytes, eosinophils, and plasma cells. However, according to the 2012 consensus statement on the pathology of IgG4-mediated disease, the number of IgG4⁺ cells or the IgG4:IgG cell ratio are of secondary importance to the finding of characteristic histopathologic features: dense lymphoplasmacellular infiltrate, storiform fibrosis, and obliterative phlebitis.²⁹⁷

IgG4-RELATED DISEASE

This newly recognized fibroinflammatory condition was first noted in patients with autoimmune pancreatitis, but it can occur in virtually any organ system, including the skin. It often presents as tumefactive lesions at multiple sites. Cutaneous involvement has included indurated, pruritic plaques,²⁹⁸ nodules, or prurigo nodule-like lesions.²⁹⁹ These lesions can occur in virtually any site, but they have a propensity for the head and neck, particularly the periauricular, cheek, and mandibular areas. Lymphadenopathy is common.³⁰⁰ Treatments that have been employed include thalidomide³⁰¹ and rituximab.³⁰²

Histopathology

Guidelines for the diagnosis of IgG4-related disease were established at an international symposium held in Boston in 2011.²⁹⁷ The three key histopathologic features are dense lymphoplasmacellular infiltrates, fibrosis that at least focally displays a storiform configuration, and/or obliterative phlebitis by a dense lymphoplasmacytic infiltrate. The lymphocytes are mainly T cells, but scattered aggregates of B cells are also identified.²⁹⁷ Other supportive features include phlebitis without luminal obliteration and increased numbers of eosinophils. Confident diagnosis requires two of the three major histopathologic features. IgG4 immunostaining is considered essential, with varying cutoff numbers depending on the organ system; for skin, this number is >200 IgG4⁺ cells/high-power field. An IgG4:IgG ratio of >40% is also considered important but is not by itself considered sufficient evidence for IgG4-related disease. Because the published data on cutaneous disease were limited at the time of this symposium, it was believed that additional evidence, such as serum IgG4 level (>135 mg/dl), would be necessary to establish the diagnosis with certainty (Fig. 40.10).²⁹⁷

ANGIOPLASMOCELLULAR HYPERPLASIA

Two cases of the apparently unique condition of angioplasmocellular hyperplasia have been reported. Lesions are composed of a proliferation of small blood vessels, some with vacuolated cytoplasm, and a mixed inflammatory cell infiltrate with a predominance of polyclonal plasma cells.³⁰³ The lesions presented as solitary nodules on the trunk. The author has also seen a case.

MAST CELL INFILTRATES

Although an increase in mast cells is seen in a variety of inflammatory dermatoses and some tumors, the presence of large numbers of these cells is almost confined to mastocytosis. Aspects of the normal mast cell are considered before the pathological conditions are described.

Mast cells

Mast cells, which measure 8–15 μ m in diameter, are round, oval, or fusiform in shape and have a central nucleus and cytoplasm that contains lightly basophilic granules.³⁰⁴ The granules stain metachromatically with the toluidine blue and Giemsa methods. They are orthochromatic (a mixture of blue and red) with an Alcian blue-safranin method³⁰⁵ and orange-red using an enzymatic method (chloroacetate esterase).³⁰⁶ In formalin-fixed material, toluidine blue may fail to stain up to 20% of mast cells.^{307,308} Carnoy’s medium appears to be a better fixative than formol saline for their demonstration.³⁰⁵ Mast cells express tryptase, leukocyte common antigen (CD45), CD43, CD68, MCG-35,³⁰⁹ 3G5,³¹⁰ and CD117, the c-kit encoded tyrosine kinase receptor protein.^{311,312} Microphthalmia transcription factor (MITF) has also been detected in mast cells.³¹³

The role of genetics in mast cell proliferations has centered on the *KIT* proto-oncogene (formerly *c-kit*), which, as mentioned previously, encodes a tyrosine kinase transmembrane receptor that is expressed on many cells, including mast cells, hemopoietic stem cells, and melanocytes.³¹⁴ Its role in piebaldism is mentioned elsewhere (see p. 322). The *KIT* mutations have been found in sporadic adult mastocytosis and in children at risk for extensive or persistent disease.^{315–318} A new germline *KIT* mutation has been found in a Chinese family with diffuse cutaneous mastocytosis. It is located in an immunoglobulin loop of the *KIT* protein, which may produce a gain-of-function effect and resultant overactivation of mast cells.³¹⁹ *KIT* mutations are not found in typical pediatric mastocytosis; however, solitary mastocytomas in the pediatric population are frequently associated with *KIT* activating mutations.³²⁰ The *KIT* gene has been localized to chromosome 4q11–q12.^{314,321}

In the skin, mast cells are usually found in the dermis with some accentuation around the superficial vascular plexus and appendages.^{308,322} They vary in number in the skin of different parts of the body, being most abundant in that of the scrotum.³²³ They are more common in acral sites than in central sites such as the abdomen.³²⁴ On average, there are approximately 7000 mast cells/mm³ of skin.³²⁵ Mast cells in the mucosa are smaller and contain fewer granules than those in the dermis.³²⁶ Mast cells are increased in the upper dermis in more than one-third of healthy volunteers sitting in front of television and personal computer screens.³²⁷ The significance of this finding is uncertain.

On ultrastructural examination, the cytoplasm of mast cells contains 80–300 membrane-bound granules, which are modified lysosomes with a highly structured internal architecture and which appear in sections as whorls or scrolls.³²⁸ Mast cell granules are larger in black skin than in white skin. This larger size appears to result from fusion of granules.³²⁹ Other organelles include mitochondria, lipid droplets,

Figure 40.10 IgG4-related disease. (A) Low-power view shows dense lymphoplasmacellular infiltrates and fibrosis with a somewhat storiform configuration. (Immunohistochemical staining with antibody to IgG4)

microfilaments, and, rarely, melanosomes.³³⁰ There are numerous microvilli projecting from the cell surface, and in mastocytosis these interdigitate with the projections of adjacent cells.³²⁸

Mast cells, which are derived from a bone marrow stem cell that expresses CD34, produce a variety of pharmacologically active agents that may be preformed or may form in the cytoplasmic granules in response to various stimuli.^{326,331–333} These agents include substances with vasoactive and smooth muscle contracting properties such as histamine, leukotrienes (B_4 , C_4 , D_2), and prostaglandin D_2 . These substances may be responsible for the pruritus, flushing, and syncope that sometimes occur in mast cell disease.³²⁶ Mast cells also manufacture chemotactic factors, enzymes (neutral proteases, acid hydrolases), and heparin. Mast cell degranulation, with release of these substances, is a calcium-dependent process triggered by chemical, physical, and immunological stimuli.³³¹ Mast cells have numerous surface receptors for the Fc part of IgE, and this is responsible for mediating their immunological degranulation.^{331,334} One of these receptors (FcεRI), on stimulation, results in the release of an array of cytokines, including various interleukins, IFN- γ , tumor necrosis factor (TNF)- α , and

GM-CSF.³³⁵ Other categories of surface receptors are present, including cytokine receptors and integrins.

An aspect of mast cell physiology that has largely been ignored is the fact that mast cells can secrete mediators without overt degranulation.³³⁶ They are also involved in a variety of neuroinflammatory diseases, especially those worsened by stress. In these circumstances, mast cells are activated by a variety of substances that stimulate mast cells to secrete mediators, without overt degranulation.³³⁶

The exact role of mast cell growth factor (MGF) in humans remains to be clarified. It is produced by keratinocytes and fibroblasts. It stimulates not only mast cell proliferation but also melanocyte proliferation and melanin pigment production *in vitro*.³³² This might explain the hyperpigmentation overlying mast cell lesions.

Mast cell hyperplasias

Mast cells appear to participate in almost all diseases of connective tissue. They are present in wound healing, keloids, chronic inflammation, parasitic infestations, urticarias, atopic eczema, lichen planus,

psoriasis, Behçet’s syndrome, pretibial myxedema, scleroderma, and lichen simplex chronicus – to name just some of the conditions in which mast cells are increased.^{325,328,335} They are also increased in the stroma of neurofibromas and other neural tumors and also in mycosis fungoides and basal cell carcinomas.³²⁸ Mast cells are sometimes found in the epidermis in various dermatoses.³³⁷

Mast cell degranulation has been incriminated in the pathogenesis of the pruritus that occurs in polycythemia rubra vera.³³⁸ This process has also been suggested as a possible cause of the pruritus in chronic renal failure, although in one study there was no correlation between mast cell numbers and the presence or absence of pruritus in patients undergoing hemodialysis for chronic renal failure.³³⁹ Furthermore, antihistamines are unhelpful in controlling the symptoms.^{340,341}

MASTOCYTOSIS

Mastocytosis comprises a spectrum of related diseases in which there is an increase in mast cells in one or more organs.³²⁶ It usually occurs as a sporadic disease that is often transient and limited in children and progressive in adults.^{317,342,343} There may be symptoms, such as pruritus, related to the release of various products from these cells.

Two *KIT* mutations at the 560 and 816 loci have been demonstrated to result in *KIT* autoactivation, and they are believed to be responsible for increased mast cells arising originally from the bone marrow.^{344,345} Patients with adult-onset mastocytosis and those with associated hematological diseases usually express activating mutations of *KIT*.³⁴⁶ Monoclonality has been reported.³⁴⁷

The WHO variants of mastocytosis are shown in Table 40.3. This classification focuses on the hematological manifestations of the disease and not the cutaneous ones.³⁴⁸ Accordingly, a more traditional classification is used, as follows:

- **Cutaneous mastocytosis**
 - Urticaria pigmentosa
 - Solitary mastocytoma
 - Diffuse cutaneous mastocytosis
 - Telangiectasia macularis eruptiva perstans (TMEP)
- **Systemic mastocytosis**
 - With cutaneous lesions
 - With extracutaneous lesions only
- **Malignant mast cell disease**
 - Malignant mastocytosis
 - Mast cell leukemia.

Table 40.3 World Health Organization variants of mastocytosis

Cutaneous mastocytosis (CM) - Maculopapular CM - Diffuse CM - Mastocytoma of skin
Indolent systemic mastocytosis (SM) - Smoldering SM - Isolated bone marrow mastocytosis
Systemic mastocytosis with an associated clonal hematological non-mast cell lineage disease (MCD-AHNMD)
Aggressive systemic mastocytosis With eosinophilia
Mast cell leukemia (MCL) Aleukemic MCL
Mast cell sarcoma
Extracutaneous mastocytoma

Urticaria pigmentosa

Urticaria pigmentosa (maculopapular cutaneous mastocytosis in the WHO classification) is the most common clinical variant of mastocytosis, accounting for approximately 80% of all cases.^{346,349,350} It usually presents as a generalized eruption of multiple red-brown macules, or rarely papules, predominantly affecting the trunk but sometimes also the extremities and head. There may be few lesions, which are widely scattered, or hundreds. They are pruritic in less than 50% of cases, although in the majority of cases lesions will develop a wheal and flare when rubbed (Darier’s sign).³²³ Onset of urticaria pigmentosa is in the first 4 years of life in 75% of cases.³⁵¹ Childhood cases have a good prognosis, usually without the occurrence of systemic involvement.^{352,353} Most lesions clear by puberty in 80% of affected individuals, although lower clearance rates have been reported.³⁵⁴ Vesiculation is a common transient change in lesions of infancy and childhood.^{355,356} Adult-onset disease is marked by persistence of lesions and the development of systemic disease in approximately 40% of cases.^{331,357–359} Adults with extensive cutaneous disease experience more pruritus and flushing than those with less extensive disease.³⁶⁰ Bone marrow involvement is common in adults with cutaneous mastocytosis.³⁶¹ A scoring system that reflects the extent of cutaneous involvement, and the symptoms and activity of lesions, has been developed.³⁶²

Rare clinical presentations of urticaria pigmentosa include a congenital or early onset bullous form,^{316,363–368} unilateral swelling of the vulva,³⁶⁹ a nodular variant,³⁴⁵ a scarring alopecia,³⁷⁰ a nevoid form distributed along Blaschko’s lines,³⁷¹ the presence of yellowish lesions resembling xanthoma or pseudoxanthoma elasticum (xanthelasmoid mastocytosis);^{372–376} and urticaria, dermatographism,³⁷⁷ massive peripheral eosinophilia,³⁷⁸ or intractable pruritus without any obvious lesions.³⁷⁹ Bullous mastocytosis resembling staphylococcal scalded skin syndrome has been reported.³⁸⁰ Urticaria pigmentosa has been associated with multiple myeloma,³⁸¹ germ cell tumors of the ovary,³⁸² Wilms’ tumor,³⁸³ HIV infection,³⁸⁴ bilateral neurosensory hearing loss,³⁸⁵ and juvenile xanthogranuloma (JXG).³⁸⁶ Sporadic familial cases occur.^{364,387–390}

The primary objective of treatment in all categories of mastocytosis is to control symptoms of mast cell ‘degranulation’ and to block mast cell proliferation.³⁹¹ Both these goals are achieved with PUVA therapy and with UVA-1 phototherapy.³⁹¹ In systemic mastocytosis, therapy with the tyrosine kinase inhibitor imatinib inhibits *KIT* associated with the *FIP1L1–PDGFRA* fusion oncogene but not the more common *KIT* D816V mutation.^{345,392} Other treatment options for systemic disease are beyond the scope of this book; they have been reviewed elsewhere.^{392,393}

Solitary mastocytoma

Solitary lesions account for approximately 10% or more of childhood mastocytoses.^{342,394} They may occur anywhere on the body, but there is a predilection for the trunk and wrists. The palm is a rare site of involvement.^{395,396} Small solitary lesions are sometimes called ‘mast cell nevi’, and the term ‘mastocytoma’ is reserved for larger nodular lesions, which may measure up to 3 cm in diameter.³³¹ A combined mastocytoma–junctional nevus has been reported.³⁹⁷ It may have resulted from the synchronous proliferation of two cell types in the one field rather than being a collision tumor.³⁹⁷ Solitary mastocytomas may be associated with extralesional symptoms, including pruritus, flushing, headaches, and gastrointestinal symptoms.³⁹⁸ Solitary lesions tend to involute spontaneously, and there is usually no indication for surgical removal. This regression is mediated by loss of proliferating activity of mast cells, an increase in apoptotic mast cells, and increased expression of stem cell factor in remaining mast cells.³⁹⁹ The latter finding is difficult to explain.

Diffuse cutaneous mastocytosis

Diffuse cutaneous mastocytosis is a rare variant that usually begins in early infancy with thickening of the skin, which may be erythematous or yellow-brown in color.^{346,400–403} Pruritus and blistering are common, and the bullae that form are more persistent than in urticaria pigmentosa of childhood. Leathery (pachydermatous) lesions may be present.^{317,404} A case of generalized bullae in diffuse cutaneous mastocytosis has been reported.⁴⁰⁵ Nodules may develop within the thickened skin, but this does not necessarily indicate a poor prognosis.⁴⁰⁶ Systemic involvement is common.³¹⁷

TMEP

TMEP is the universally accepted short designation for telangiectasia macularis eruptiva perstans, a rare adult form of mastocytosis with a high incidence of systemic involvement.^{407,408} Childhood cases and two familial series with childhood onset have been reported.^{409–412} Unilateral^{413,414} and linear⁴¹⁵ lesions have been described. Erythema and telangiectasia are found in faintly pigmented macules on the trunk and proximal parts of the extremities.³⁰⁴ Facial involvement has been reported.^{416,417} Multiple myeloma is a rare association. It has been suggested that aberrations in the *KIT* pathway may explain the abnormal proliferation of both lineages.⁴¹⁸ TMEP has also been associated with a myeloproliferative disorder.⁴¹⁹

Systemic mastocytosis

In systemic mastocytosis, there is a proliferation of mast cells in various tissues apart from, or in addition to, the skin.⁴²⁰ Systemic mastocytosis may develop in childhood cases of urticaria pigmentosa that persist beyond puberty and also in approximately 40% of adults with urticaria pigmentosa, usually of long standing.^{351,357,421} It may also be associated with TMEP.^{422,423} A case of systemic mastocytosis with diffuse cutaneous involvement and hematological disease presenting *in utero* has been reported.⁴²⁴ Cutaneous lesions are most common on the trunk, although all skin areas, including mucous membranes, may be involved. Papillomatous and verrucous lesions are rare findings.⁴²⁵ Recurrent syncope and anaphylaxis were the presenting features of one pediatric patient.⁴²⁶ Thrombocytosis is another rare manifestation of systemic mastocytosis.⁴²⁷ In a recent study by Berezowska *et al.*, it was found that virtually all patients with adult-onset mastocytosis in the skin had systemic involvement.⁴²⁸ This was determined by using the WHO diagnostic criteria for systemic mastocytosis (see later) (Table 40.4); in addition, KIT D816V⁺ mast cells were found in all tested bone marrow biopsies using highly sensitive molecular methods.⁴²⁸

The bone marrow is the tissue most frequently involved in systemic mastocytosis, followed by the liver, spleen, gastrointestinal tract, lymph nodes, and, rarely, other organs.^{420,429} Sometimes bone marrow is the only tissue involved besides the skin. Systemic mast cell disease without skin involvement is quite uncommon, and it is often difficult to diagnose.^{407,420} However, the urinary excretion of the histamine metabolite methylimidazoleacetic acid is increased in cases of systemic mastocytosis.^{326,430} Van Doormaal *et al.* found that in suspected patients without skin involvement, the risk of indolent systemic mastocytosis is very low if tryptase levels are <10 µg/L; if levels are ≥10 µg/L, the risk is low if methylimidazoleacetic acid and methylhistamine levels are normal, but the risk is high if these metabolites are elevated.⁴³¹ Additional risk factors include male gender and insect venom anaphylaxis.⁴³¹ Flow cytometry on bone marrow samples and the use of serum or marrow-blood tryptase levels may assist in making a diagnosis in indolent cases without cutaneous involvement.^{360,432,433} High-sensitivity flow cytometry is also effective in determining bone marrow involvement with systemic mastocytosis by detecting aberrant CD2/CD25

Table 40.4 WHO criteria for systemic mastocytosis

Major criterion	Minor criteria
Multifocal, dense aggregates of mast cells (15 or more) detected in sections of bone marrow, confirmed by tryptase immunohistochemistry or other special stains	a. In a biopsy specimen, more than 25% of the mast cells in the infiltrate have atypical morphology, or, of all the mast cells in an aspirate smear, more than 25% are immature or atypical. b. Mast cells co-express CD117 and CD2 and/or CD25. c. Detection of <i>KIT</i> point mutation at codon 816 in bone marrow, blood, or other extracutaneous organs. d. Serum total tryptase persistently >20 ng/ml (not a valid criterion in cases of systemic mastocytosis with associated clonal hematologic non-mast cell lineage disease).

The diagnosis of systemic mastocytosis may be rendered if one major plus one minor or three minor criteria are fulfilled.

expression by CD117-gated mast cells and by recognition of a discrete CD117-bright population.⁴³⁴

Systemic mastocytosis may progress to malignant mastocytosis and/or mast cell leukemia. Various lymphoproliferative and myeloproliferative conditions may sometimes eventuate,^{435–437} particularly myelogenous leukemia.^{407,438,439} It has also been associated with a lymphocytic lymphoma.⁴⁴⁰ The hypereosinophilic syndrome is a rare association.⁴⁴¹ Cutaneous lesions regress in approximately 10% of older patients who have systemic mastocytosis.⁴⁴² In patients with an associated hematological condition, this regression may be accompanied by progression of the hematological disease.⁴⁴² In patients with systemic mast cell disease without associated hematological disorders, the bone marrow mast cell burden, bone marrow eosinophilia, and serum alkaline phosphatase levels are of prognostic significance.⁴⁴³ It has been claimed that up to one-third of individuals with systemic mastocytosis may progress to malignancy, but this seems unduly pessimistic in light of other studies, one of which showed that the clinical course of systemic mastocytosis was stable over a period of 10 years in all those followed.³⁵⁷

A small proportion of cases are clonal. This is more common in cases with associated eosinophilia. They may carry the *FIP1L1-PDGFR*A fusion oncogene, which results from an interstitial deletion of chromosome 4q12, thereby generating an active PDGFR tyrosine kinase.³⁹²

Malignant mast cell disease

There may be a progressive proliferation of atypical mast cells leading to the enlargement of various organs. This usually follows systemic mastocytosis, and it has been called malignant mastocytosis and mast cell reticulosis.⁴⁴⁴ The extremely rare mast cell sarcoma is a localized mass of malignant mast cells in the soft tissues.^{444,445} Mast cell leukemia may develop in any of these settings or as a progression of systemic mastocytosis.⁴⁴⁴ There is extensive bone marrow infiltration and atypical mast cells circulating in the peripheral blood.⁴⁴⁶ It has a poor prognosis.³⁰⁴

Histopathology³⁰⁴

The histological pattern of mastocytosis is similar regardless of the clinical type, although there are major variations in the number of mast cells present.⁴⁴⁶ The infiltrate is predominantly in the upper third of the dermis, at times in proximity to the dermoepidermal junction (Fig. 40.11).⁴⁴⁶ In the usual macular lesions of *urticaria pigmentosa*, the

Figure 40.11 Urticaria pigmentosa. (A) Mast cells fill the papillary dermis. (B) A higher power view of the mast cells. (H&E)

infiltrate may vary from sparse and perivascular to larger aggregates of mast cells. Perivascular mast cells may be cuboidal or fusiform in shape, whereas those in larger aggregates tend to be cuboidal (Fig. 40.12). A scattering of eosinophils is usually present, and there may be superficial edema in lesions that are rubbed prior to removal. Basal hyperpigmentation is a useful clue to the diagnosis of urticaria pigmentosa and some other types of mastocytosis.

In *solitary mastocytoma*, there are dense aggregates of mast cells in the dermis, sometimes extending into its deeper levels and even into the subcutis (Fig. 40.13).³⁰⁴ Cells with bilobed or multilobed nuclei were noted in one case.⁴⁴⁷ Eosinophils may be present in small numbers; massive infiltration is a rare occurrence.^{448,449} Localized necrobiosis and stromal fibrosis have been reported.^{450,451} In *TMEP*, there may be only subtle alterations in mast cell numbers; the cells tend to be fusiform and loosely arranged around the dilated vessels of the superficial plexus (Fig. 40.14). Eosinophils are usually absent.

Dermoscopy of TMEP lesions shows a reticular vascular pattern and/or a pigmented network.⁴⁵²

In *diffuse cutaneous mastocytosis*, there are loosely arranged mast cells throughout the dermis.⁴⁰⁶ Fibrosis is sometimes present.⁴⁰⁴ The mast cells are deeper in the dermis in the xanthomatous form.

Superficial edema leading to subepidermal vesiculobullous changes is common with mast cell lesions of infancy and childhood.⁴⁵³ There

Figure 40.12 Urticaria pigmentosa. Numerous mast cells are present in the upper dermis. There is also mild hyperpigmentation of the basal layer. (Toluidine blue)

Figure 40.13 Solitary mastocytoma. (A) Mast cells fill the dermis. (H&E) (B) The cells express CD117. (Immunoperoxidase stain)

Figure 40.14 Telangiectasia macularis eruptiva perstans (TMEP). (A) The mast cells are predominantly perivascular in location. The blood vessels are not as telangiectatic as usual. (H&E) (B) Mast cells surround dilated vessels in the upper dermis. (Immunoperoxidase stain for CD117)

may be eosinophils, mast cells, and occasional neutrophils within the bullae, and there may also be a diffuse aggregate of mast cells in the upper dermis below the band of edema or the blister cavity.

Quantitative studies have shown that the number of mast cells in the cutaneous lesions of mastocytosis is from 2 to 160 times that in the adjacent normal skin.^{307,454-456} Normal skin may contain up to 20 mast cells per high-power ($\times 40$) field. In TMEP, in which the increase may be subtle, it is often useful to have some normal skin at one end of the biopsy for comparison with lesional skin.³⁰⁴ Qualitatively, the mast cells in mastocytosis resemble normal mast cells, with little atypia and only minor changes detected by morphometry.^{457,458} They give the staining reactions described for normal mast cells; the choice of stain (toluidine blue, astra blue, Giemsa, or chloroacetate esterase) often depends on individual preference. Mast cell tryptase can also be used.^{343,459} Immunohistochemistry for CD117 and CD68 has been used.^{311,460} CD117 gives a clearer staining pattern than some of the earlier histochemical methods. MITF is not commonly sought.⁴⁶¹ Nevertheless, its presence, along with staining for mast cell tryptase, effectively discriminates mast cell disease from myeloid leukemia

cutis.⁴⁶² In some cases of malignant mastocytosis, the cells lack metachromatic granules and fail to stain with routine methods. The anti-tryptase antibody G3 will stain mast cells in these circumstances.⁴⁶³

The expression of CD25 on cutaneous mast cells from adult patients presenting with urticaria pigmentosa is predictive of systemic mastocytosis.⁴⁶⁴

Electron microscopy

The ultrastructural features of normal mast cells were described previously. In mastocytosis, the cells have prominent surface projections that interdigitate with adjacent cells. Other reported findings include giant cytoplasmic granules^{465,466} and mast cells with endocytic and autophagic vacuoles.⁴⁶⁷ A blue nevus combined with a mastocytoma has been reported, with some cells containing both melanosomes and mast cell granules.⁴⁶⁸

Differential diagnosis of cutaneous mastocytosis

A major diagnostic problem is recognizing that a lesion represents mastocytosis when dermal infiltration is sparse. This problem arises particularly in connection with telangiectatic mastocytosis, in which only a few perivascular spindle cells may be observed, differing only slightly from their appearance in normal skin. Diagnosis then depends on the recognition that virtually all of the infiltrating cells are mast cells – a determination aided by special stains such as chloroacetate esterase, CD117, and tryptase. A second major issue is the distinction of primary mast cell disorders from inflammatory dermatoses in which mast cells can be fairly numerous. Examples of such conditions include spongiotic (eczematous) dermatitis, lichen planus, and erythema multiforme. Recognition of defining features of these other disorders (spongiosis in eczematous dermatoses, interface changes in lichen planus, and keratinocyte apoptosis and vacuolar degeneration of the basilar layer in erythema multiforme), together with an appreciation of the polymorphous nature of the dermal infiltrates, should ordinarily permit recognition of those disorders. In addition, computerized image analysis of chloroacetate esterase-stained sections has shown more numerous and larger mast cells in skin lesions of adults with mastocytosis than in either inflammatory dermatoses or normal skin.⁴⁵⁶

A second issue is the separation of mastocytosis from lesions whose constituent cells bear a resemblance to mast cells. One of these, Langerhans cell histiocytosis, occurs in infants and adults, and it may present with lesions containing numerous rounded to cuboidal cells and eosinophils. However, those cells lack the characteristic cytoplasmic granules of mast cells; possess folded, indented, or reniform nuclei; and often permeate the epidermis. They fail to stain as mast cells and instead express S100 protein, CD1a, peanut agglutinin, and langerin. The cells of melanocytic nevi can sometimes bear a close resemblance to mast cells. However, in contrast to mast cells, nevomelanocytes often show nesting along the dermal–epidermal junction and tend to be aggregated in nests, cords, or other groupings within the dermis. They lack the characteristic cytoplasmic granules or staining characteristics of mast cells and are characteristically S100⁺. Occasionally, lesions of juvenile xanthogranuloma (JXG) without lipidized cells or Touton giant cells can resemble mastocytosis, but unlike the latter, the cells of JXG often express CD68 and factor XIIIa and fail to stain with mast cell markers. Finally, until recently, it has not been possible to determine from the findings on skin biopsy which cases of adult cutaneous mastocytosis may be associated with systemic disease. However, it is known that in patients with systemic mastocytosis, neoplastic cells in the bone marrow often show aberrant surface expression of CD25. Recently, Hollmann and colleagues showed that cutaneous mast cells from all patients studied who had systemic mastocytosis expressed CD25, whereas only 25% of those with limited cutaneous mastocytosis expressed this antigen.⁴⁶⁴

BRACHIORADIAL PRURITUS

Brachioradial pruritus is a rare dermatosis that presents with a chronic intermittent intense pruritus localized to the elbow region in the vicinity of the brachioradialis muscle.^{469–472} Sometimes the lateral surface of the upper part of the arm, just below the midpoint, is involved.^{473,474} The pruritus, which may be unilateral or bilateral, is often accompanied by a burning sensation.⁴⁶⁹ The itch feels ‘deep’. It progressively worsens toward evening.⁴⁷⁵ The application of ice packs provides relief. This is a diagnostic feature, not a recommended treatment.⁴⁷⁶ Several members of the one family have been affected.⁴⁷⁷ Their disease was characterized by symptom-free periods. Affected individuals are sometimes referred to a psychiatrist because there is little to see clinically except for mild poikilodermatous mottling suggestive of solar damage.⁴⁷⁴

This condition is seen in white people living in tropical and subtropical climates, suggesting that exposure to the sun is of some etiological importance.^{469,478} It has therefore been regarded in the past as a solar dermatopathy and part of the spectrum of solar pruritus.^{479–482} Interestingly, there is a recent report of a patient who had an apparent photoallergic reaction to varenicline (a nicotinic receptor partial agonist used in treating nicotine addiction) that mimicked brachioradial pruritus.⁴⁸³ However, in some patients clinical improvement has been achieved by cervical spine manipulation, suggesting that in these patients there may be a component of nerve damage from cervical spine disease.^{484–486} It has also been associated with a spinal cord tumor.⁴⁸⁷ The current consensus view is that ultraviolet radiation may act as a trigger in some patients, although underlying neurological cervical injury is also an important etiological factor.^{488–490} In one series, the disease could be attributed to a neuropathy in all patients.⁴⁹¹ Its etiological similarity to notalgia paresthetica (see p. 342) has been noted.⁴⁹²

Neuropathic scrotal pruritus is another similar condition. It is due to a lumbosacral radiculopathy.⁴⁹³

Brachioradial pruritus is often refractory to treatment with topical or oral corticosteroid and with antihistamines. A controlled trial showed no benefit from capsaicin.⁴⁹⁴ Several cases have been successfully treated with gabapentin, an anticonvulsant used also in the treatment of neuropathic pain.⁴⁹⁴

Histopathology

Little may be observed on a casual examination of a biopsy. Closer inspection will usually reveal mild, patchy hyperpigmentation of the basal layer with minimal melanin incontinence, mild telangiectasia of superficial blood vessels, and occasional mononuclear cells around dermal vessels and appendages (Fig. 40.15).⁴⁷⁴ There is also some solar elastosis.

Stains for mast cells reveal that many of the mononuclear cells are mast cells, and although their increase in number is marginal, they are usually quite plump and contain numerous cytoplasmic granules.⁴⁷⁴ This applies particularly to the mast cells in the vicinity of the pilosebaceous follicles and eccrine glands. This is one reason for its inclusion here.

HISTIOCYTIC INFILTRATES (NON-LANGERHANS CELL)

The histiocytic infiltrates are a heterogeneous group of disorders that were also known, in the past, as the ‘non-X histiocytoses’ because the infiltrating cells lack Birbeck granules (Langerhans bodies) and other markers of Langerhans cells, which are the cells found in histiocytosis X.^{495–497} Contemporary classifications now regard Langerhans cells as one class of histiocyte, indicating that our concepts have gone ‘full

Figure 40.15 Brachioradial pruritus. A few lymphocytes and mast cells surround the telangiectatic vessels in the upper dermis. (H&E)

circle’. For convenience, the Langerhans cell histiocytes are considered later in this chapter.

Histiocytes

The histiocyte is a somewhat controversial cell that still lacks precise definition.^{498–501} The term ‘histiocyte’ has been used in the past for almost any cell with a reniform or indented nucleus, a diameter of 10–25 μm , and a nuclear/cytoplasmic ratio of approximately 1:1.⁴⁹⁸ The advent of immunohistochemistry, with the use of various monoclonal antibodies, has allowed the more precise characterization of cells that resemble each other morphologically. These studies have confirmed that the term ‘histiocyte’ has been used in the past for a variety of cells, including Langerhans cells and other immune accessory cells and certain subsets of T and B lymphocytes.⁴⁹⁸

In 1997, the Histiocyte Society in conjunction with the WHO Committee on Histiocytic/Reticulum Cell Proliferations published what they called a ‘Contemporary Classification of Histiocytic Disorders’.⁵⁰² They defined histiocytes as ‘a group of immune cells, familiar to morphologists, that includes macrophages and dendritic cells’. They noted that macrophages and dendritic cells were polar representatives of one common regulatory system. The origin of the various histiocytes is still controversial, but it appears that the macrophage, the indeterminate cell, and the Langerhans cell are derived from the CD34⁺ hemopoietic progenitor, whereas the dermal dendrocyte is derived from cutaneous mesenchymal (fibroblastic) precursors, although a hemopoietic source has also been proposed.⁵⁰² The various types of histiocytes express different antigens that assist in their distinction. They are shown in Table 40.5.

Common usage today considers the histiocytes as tissue macrophages derived from blood monocytes. They act as professional phagocytes or antigen-presenting cells. They can have different phenotypes depending on the tissue in which they are found.⁵⁰³ Both phagocytic and antigen-presenting histiocytes are able to produce inflammatory cytokines and mediators.⁵⁰³

Whereas Langerhans cells and indeterminate cells stain positively for S100 protein and CD1a, cells of the monocyte–macrophage system stain with the CD11B, CD11C, CD14, CD68, HAM-56, and Mac387 antibodies, although Mac387 lacks sensitivity.^{502,504–506} Lysozyme may also be present in these cells. Another marker, MS-1, a high-molecular-weight extracellular protein specific for sinusoidal endothelial cells and dendritic perivascular macrophages, is expressed by the cells of the various histiocytic tumors but not by Langerhans cells or the palisading

Table 40.5 Distinguishing features of cutaneous histiocytes	
Cell type	Features
Macrophage	CD45, CD14, CD68, CD163, lysozyme positive Also, often CD11b, CD11c, HAM-56, Mac387 positive S100, CD1a, factor XIIIa negative
Dermal dendrocyte	Factor XIIIa, CD45, CD68 positive S100, CD1a negative
Indeterminate cell	CD45, S100, CD1a positive Factor XIIIa negative (?) Birbeck granules absent
Langerhans cell	CD45, S100, CD1a, CD101 positive Factor XIIIa negative Birbeck granules present

Macrophage-related	
Hemophagocytic syndromes (primary and secondary)	
Rosai–Dorfman disease	
Solitary histiocytoma with macrophage phenotype	
Malignant disorders	
Monocyte-related (various leukemias)	
Dendritic cell-related histiocytic sarcoma	
Macrophage-related histiocytic sarcoma	

^aThis classification is based on the Histiocyte Society/WHO classification of 1997, and it excludes noncutaneous diseases. (Med Pediatr Oncol 1997; 29: 157–166).

histiocytes of granuloma annulare.⁵⁰⁷ Although the non-Langerhans histiocytes are usually considered to be S100[−], scattered cells in some tumors may be positive.⁵⁰⁸

As additional immunohistochemical studies are published, using expanded panels of monoclonal markers, it may become necessary to recategorize some of these entities.⁵⁰⁹ Furthermore, some cases have been reported that defy orderly classification, despite being studied by means of various immunohistochemical markers.^{510–515}

As mentioned previously, a new classification of histiocytic disorders was published by the Histiocyte Society/WHO group in 1997.⁵⁰² As it applies to all body systems, a modified version covering the skin is shown in Table 40.6. It can be seen that many of the diseases discussed in this section are dismissed as ‘related disorders’ of JXG. Unfortunately, it is difficult to classify all of these conditions into one of the various categories of the histiocytoses because of conflicting immunohistochemical results for some of the rarer entities. An attempt is made to do this here, based on current knowledge. Before doing so, it is worth noting the approach of Zelger and colleagues to this confusing topic.⁵¹⁶ They attempted a morphological classification of most of the non-Langerhans histiocytoses of presumed dendritic origin. A modified version of their classification is shown in Table 40.7.

The various non-Langerhans histiocytoses are discussed in the order given here. The categorization is based on the author’s interpretation

Table 40.7 Morphological classification of non-Langerhans cell histiocytoses	
Cell type	Histiocytoses
Vacuolated	Juvenile xanthogranuloma (mononuclear type) Benign cephalic histiocytosis Generalized eruptive histiocytosis Progressive mucinous histiocytosis
Xanthomatized	Papular xanthoma Xanthoma disseminatum (rare)
Spindle-shaped	Spindle cell xanthogranuloma Progressive nodular histiocytosis Progressive mucinous histiocytosis
Scalloped	Xanthoma disseminatum
Oncocytic	Multicentric reticulohistiocytosis
Mixed	Juvenile and adult xanthogranuloma Reticulohistiocytoma Progressive mucinous histiocytosis

of the current Histiocyte Society/WHO classification and supplemented by published papers,^{502,516,517} notwithstanding the problems posed by some apparent discrepancies in published immunohistochemical results. Note that a comparatively recent paper suggested that the plasmacytoid monocyte, rather than the dermal dendrocyte, is the cell of origin of JXG.⁵¹⁸ Other tumors in this same category would presumably have a similar origin.

 - Intravascular/intralymphatic histiocytosis.

Regressing atypical histiocytosis was formerly included with this group, but it is now regarded as a T-cell lymphoma on the basis of immunohistochemistry.

It is becoming increasingly apparent that there is considerable overlap between the clinical and histopathological features of the

Table 40.8 Clinical groups of non-Langerhans cell histiocytoses

Predominantly affecting skin	Juvenile xanthogranuloma, cephalic histiocytosis and others
Skin + major systemic involvement	Xanthoma disseminatum
Primarily involve extracutaneous sites	Erdheim–Chester disease Rosai–Dorfman disease Sea-blue histiocyte syndrome

various cutaneous histiocytoses, suggesting that they possibly represent one disease ‘entity’ with a wide spectrum of clinical presentations rather than many discrete disorders.^{519–521} This is particularly so for the non-Langerhans histiocytoses of presumed dendritic origin. Three clinical groups of non-Langerhans cell histiocytoses have been proposed (Table 40.8).⁵²²

Cases reported variously as reactive angioendotheliomatosis, intravascular histiocytosis, and cutaneous histiocytic lymphangitis consist of dilated vascular channels containing histiocytic cells. They are considered together as intravascular/intralymphatic histiocytosis at the conclusion of the histiocytic infiltrates (see p. 1161).

JUVENILE XANTHOGRAULOMA (JXG)

JXG is a normolipemic histiocytosis composed of cells originally thought to be derived from dermal dendrocytes.^{495,502,523–525} However, a subsequent study suggested that the plasmacytoid monocyte is a more likely precursor.⁵¹⁸ Solitary or multiple red-brown papulonodules, 1–10 mm in diameter or larger,^{526–528} are found on the head and neck, upper part of the trunk, and proximal parts of the limbs.^{529,530} In one series, a solitary cutaneous lesion accounted for 67% of cases; multiple cutaneous lesions were present in 7% of the patients.⁵³¹ In the series from Kiel, 81% were solitary.⁵³² The sole of the foot,⁵³³ vulva,⁵³⁴ anogenital region,⁵³⁵ finger,⁵³⁶ and proximal nail fold⁵³⁷ are rare sites. Atypical forms with extensive facial⁵³⁸ or generalized eruptions^{539–541} have been documented. A thickly crusted variant on the scalp has been described.⁵⁴² Lichenoid lesions have been reported.⁵⁴³ Plaque-like and clustered lesions also occur.^{544–546} A linear distribution is another pattern.^{547,548} In two-thirds of all cases, onset is within the first 6–9 months of life;^{549–552} approximately 5–35% are present at birth.^{532,553,554} Severe congenital systemic JXG has been reported in monozygotic twins.⁵⁵⁵ Late onset in adolescence or adult life occurs in approximately 10–30% of cases.^{556–561} The term ‘xanthogranuloma’ or ‘adult xanthogranuloma’ is used for these cases. There is a male predominance.⁵³¹ Spontaneous involution usually occurs after many months or even years; lesions persist in some individuals who develop their first lesions after the age of 20 years.^{562,563}

A small percentage of patients have ocular involvement;^{549,564} visceral, including oral, involvement is exceedingly rare.^{523,538,565–567} Rare cases involving a peripheral nerve have been reported.⁵⁶⁸ One case arose in an organoid nevus (nevus sebaceus),⁵⁶⁹ and another arose in the substance of the breast.⁵⁷⁰ JXG has been reported in association with neurofibromatosis (sometimes with associated juvenile chronic myelogenous leukemia),^{571–576} other hematological malignancies,^{577,578} Niemann–Pick disease (see p. 565),⁵⁷⁹ contralateral lymphadenopathy with a histiocytic infiltrate,⁵⁸⁰ adult T cell leukemia/lymphoma,⁵⁸¹ follicular lymphoma,⁵⁸² and urticaria pigmentosa.⁵⁸³ JXG has developed in a number of children as a sequel to Langerhans cell histiocytosis.^{584,585} In another case, an eruptive variant developed following treatment of Langerhans cell histiocytosis with chemotherapy.⁵⁸⁶ A case resembling JXG developed in a boy at puberty who had homozygous familial hypercholesterolemia, under treatment with low-density lipoprotein apheresis and drug therapy.⁵⁸⁷ An adult xanthogranuloma arose following radiation therapy of Merkel cell carcinoma.⁵⁸⁸

Figure 40.16 Juvenile xanthogranuloma. There is an admixture of several cell types forming a dense infiltrate. (H&E)

Although the etiology of JXG is unknown, studies have shown that cholesterol is the principal lipid in the lesions.⁵⁸⁹ Furthermore, there are no unusual sterols present.⁵⁸⁹ A 2007 study demonstrated clonality in one case.⁵⁹⁰ Clonality has since been found in a case of ‘aggressive’ JXG developing after a diagnosis of T cell acute lymphoblastic leukemia⁵⁹¹ and in another case of JXG associated with a clonal proliferation in the bone marrow.⁵⁹²

Simple tumor excision is the treatment of choice except in the very rare systemic form, in which multimodal chemotherapy is indicated.⁵³²

Histopathology^{529,593}

There is a nodular, poorly demarcated dense infiltrate of small histiocytes involving the dermis and sometimes the upper subcutis as well. Rarely, deep extension into skeletal muscle is present.^{594,595} The cells are polygonal or spindle-shaped and plump, and they have indistinct cytoplasmic borders. Mitoses are rare. Whereas early lesions are fairly monomorphous, with inconspicuous foam cells,^{596–601} mature lesions contain foamy histiocytes and varying numbers of Touton cells (Figs. 40.16 and 40.17). These cells have a less foamy periphery than those

Figure 40.17 Juvenile xanthogranuloma. The Touton giant cells, which are unusually large, are admixed with lymphocytes and histiocytes. (H&E)

seen in other xanthomatous conditions. They are transient elements, not present in every case, particularly in extracutaneous sites.⁶⁰² Small aggregates of foam cells may be seen in some cases, and fully xanthomatized variants also occur (Fig. 40.18). There are also scattered lymphocytes and neutrophils, rare plasma cells, and sometimes eosinophils. Lesions of longer duration will show interstitial fibrosis and proliferating fibroblasts.

Based on the review of 129 cases in the Kiel Pediatric Tumor Registry,⁵³² it appears that there is a time-dependent course in the evolution of lesions. There is an early, predominantly mononuclear infiltrate, followed by the classic Touton cell-rich stage. Finally, there is a stage with a spindle cell pattern with a variable component of mononuclear and multinucleated cells.^{532,602}

The lesion reported as a *spindle cell xanthogranuloma* is best regarded as a histological variant of the adult form of xanthogranuloma. It is composed of spindle-shaped histiocytes arranged in a storiform pattern. Other mononuclear (xanthomatized, oncocyctic, vacuolated, and scalloped) and multinucleate (Touton) histiocytes are present.⁶⁰³

The *scalloped cell xanthogranuloma* is another variant in which there is a predominance (>75% of all cells) of scalloped histiocytes. Such cells have an angulated or scalloped border, set apart from one another in a delicate fibrous matrix.⁶⁰⁴ The cytoplasm of the cells is homogeneous and slightly eosinophilic, whereas the nucleus is round to oval and large.

A mitotically active deep JXG has been reported.⁶⁰⁵

Fat stains confirm the presence of some lipid. Hemosiderin has been demonstrated in a few cases.⁶⁰⁶ The histiocytes are usually positive for CD68, HAM-56, HHF35, cathepsin B, vimentin, factor XIIIa, fascin, CD4, lysozyme, and α_1 -antichymotrypsin;⁵²⁹ they are negative for Mac387, smooth muscle actin, CD34, CD1a, and S100 protein.^{539,593} Positivity for CD163 has also been reported.⁵⁸⁸ Approximately 1–10% of the other cells in any lesion are S100+.⁶⁰⁷ Such cells are elongated or dendritic in appearance.⁵⁵⁶ Staining for the various markers listed previously may be more intense at the periphery of the lesion. Membranous staining is the predominant pattern seen with CD10.⁶⁰⁸

It has been suggested that the deep forms are derived from dermal indeterminate cells (CD1a+, S100-), but this is based on only one study.⁶⁰⁹ These two markers were not studied in a recent series of three deep cases; the cells were CD68+ and factor XIIIa+.⁶¹⁰

Unusual chromosomal aberrations were identified in the peripheral blood and bone marrow of a patient with disseminated JXG; juvenile myelomonocytic leukemia was excluded in this case.⁶¹¹

Figure 40.18 Juvenile xanthogranuloma. There is prominent xanthomatization with epidermal atrophy. (H&E)

On dermoscopy, most early evolving and fully developed xanthogranulomas have a 'setting sun' appearance – an orange-yellow background with a subtle erythematous border. The surrounding erythema decreases in the late regressive stage. Pale yellow to yellow globules appear as vacuolated cells transform to xanthomatized cells, and 'clouds' of pale yellow globules are found in the fully developed to late regressive stages. Linear and branched vessels are apparently found in all stages.⁶¹²

Electron microscopy^{524,613,614}

Ultrastructural examination of mature lesions has shown lipid vacuoles (often without a limiting membrane), lysosomes, cholesterol clefts, and myeloid bodies but no Birbeck granules. Early lesions have only a few lipid-laden cells, and there are complex interdigitations of the cell membrane.⁶¹⁵ Fibroblastic cells have also been noted in some lesions.⁶¹⁶

Differential diagnosis

It can sometimes be difficult to distinguish between JXG and Langerhans cell histiocytosis. The latter displays histiocytes with reniform nuclei and epidermal infiltration, and well-formed Touton giant cells are uncommon. In most instances, the cells of JXG are negative for

S100; in contrast to Langerhans cell histiocytosis, the occasional S100⁺ examples of JXG are negative for CD1a. Lipidized dermatofibromas also have some features in common with JXG, but the former lesions tend to feature overlying epidermal acanthosis and a characteristic ‘curlicue’ arrangement of cells. The Touton-like giant cells in dermatofibromas tend to be angulated, have some clumping of nuclei without the classic wreath-like arrangement, and have a lipid layer that often contains hemosiderin. Both dermatofibroma and JXG cells can be positive for factor XIIIa, although this stain is somewhat more likely to be strong and evenly distributed among the cells of dermatofibroma. In contrast to JXG, dermatofibroma cells tend to be positive for antibody to HLA-DR (LN3), negative for CD68, and negative for peanut agglutinin.⁶¹⁷

Morphologically, the prevalence of lipidized cells and Touton giant cells in JXG usually allows distinction from reticulohistiocytoma (RH), whose cells have characteristic ‘ground glass’ cytoplasm and nuclei with sharply defined nuclear membranes and prominent nucleoli. Nevertheless, there can be considerable immunohistochemical overlap of the two lesions. S100⁺ examples of JXG could be confused with intradermal variants of epithelioid cell (Spitz) nevi. Staining for CD68 may not allow clear-cut differentiation because melanocytic tumors sometimes express this antigen. Careful search for junctional nests or staining with other melanocytic markers such as melan-A, HMB-45, or tyrosinase may be of help in these circumstances. Staining for factor XIIIa may also be useful because most examples of JXG are at least focally positive, whereas melanocytic nevi and malignant melanomas are negative. The editor has encountered rare cases of JXG with a predominance of oncocyctic or nonlipidized cells, producing a resemblance to mastocytoma; in fact, rare cases of coexistent JXG and urticaria pigmentosa have been reported.⁵⁸³ Depending on the quality of tissue sections, simple distinction on morphologic grounds alone may not always be possible; however, negative results with stains for mast cells such as Giemsa, Leder (chloroacetate esterase), CD117, or tryptase would be helpful in supporting the diagnosis of JXG.

BENIGN CEPHALIC HISTIOCYTOSIS

Benign cephalic histiocytosis is a clinically distinct non-lipid ‘non-X’ histiocytic proliferation in children.^{618–621} Fewer than 50 cases have been reported.⁶²² It is characterized by the development of asymptomatic red-brown maculopapules, 2–5 mm or more in diameter, on the face, whence the condition may evolve to affect the neck, upper part of the trunk, arms, and other parts of the body.^{623–625} The palmoplantar regions, mucous membranes, and viscera are spared,⁶¹⁸ however, a case with diabetes insipidus has been reported.⁶²⁶ In another case, insulin-dependent diabetes mellitus developed.⁶²⁷ Spontaneous regression, complete or partial, occurs during childhood, without scarring.^{618,628} Similar lesions have been reported in an adult with T-cell lymphoma. The exact status of this case is uncertain.⁶²⁹ There is increasing evidence that benign cephalic histiocytosis is a clinicopathological variant of JXG^{630,631} or part of a spectrum with it.⁶³²

Histopathology⁶¹⁸

There is a diffuse infiltrate of histiocytes, mainly in the upper dermis and in close apposition to the undersurface of the epidermis. The cells have an oval or reniform vesicular nucleus and ill-defined pale cytoplasm.⁶¹⁹ There is usually no cytoplasmic lipid in the early stages of evolution, but xanthomatization can be seen in lesions of long duration.⁶³⁰ Occasional multinucleate histiocytes are present. There are scattered or grouped lymphocytes within the infiltrate, and there are occasional eosinophils in some lesions. The histiocytes are generally negative for S100 protein, although an S100⁺ case was recently

reported.⁶³³ They are negative for CD1a but positive for CD68, CD11b, CD14, HAM-56, and factor XIIIa.^{618,628,630}

Electron microscopy⁶¹⁸

The most characteristic feature of the histiocytes is the presence of many coated vesicles, 500–1500 nm in diameter, in the cytoplasm. Comma-shaped inclusion bodies are present in 5–30% of the histiocytes.⁶³⁴ No Birbeck granules or lipid droplets are present. Desmosome-like junctions are present between the histiocytes in densely cellular areas.⁶¹⁸

Differential diagnosis

There can be significant overlap between benign cephalic histiocytosis and other forms of non-Langerhans cell histiocytosis. For example, one reported case of eruptive histiocytoma in an adult bore a close resemblance to benign cephalic histiocytosis.⁶³⁵ A comparison of giant solitary xanthogranuloma and benign cephalic histiocytosis showed similar histopathologic features and evolutionary characteristics over time,⁶³⁰ and another case of benign cephalic histiocytosis evolving into JXG has been reported.⁶³¹ Gianotti, Alessi, and Caputo performed blinded histopathologic evaluations of specimens representing benign cephalic histiocytosis, generalized eruptive histiocytoma, papular xanthoma, and JXG. With few exceptions, these authors found a close relationship among the findings in benign cephalic histiocytosis, generalized eruptive histiocytoma, and early, non-xanthomatized JXG. This result provides another piece of evidence that these three disorders may well be part of a spectrum of a single disease process.⁶³⁶

PROGRESSIVE NODULAR HISTIOCYTOSIS

Progressive nodular histiocytosis is a normolipemic non-Langerhans cell histiocytosis in which multiple yellowish-brown papules and nodules develop on the skin and mucous membranes.^{637–640} The nodules are more common on the trunk, whereas the papules are widely and randomly distributed on the body. Both types of lesion can occur around the genitalia.⁶⁴¹ Similar lesions have been noted in a patient with acute myelomonocytic leukemia⁶⁴² and in another with chronic myeloid leukemia.⁶⁴³ It has also been reported in a patient with a hypothalamic tumor.⁶⁴⁴ It has been suggested that all these cases are variants of, or closely related to, (juvenile) xanthogranuloma. Another confusing feature is the use of the term ‘progressive nodular histiocytosis’ for cases with morphological features of multicentric reticulohistiocytosis but an absence of the usual systemic symptoms of this disorder (see later).⁵²⁴ Leonine facies have been present in the latter condition.^{524,645,646} In the initial reports of the entity under discussion, the word ‘histiocytoma’ was used instead of ‘histiocytosis’ in the title.

Histopathology^{598,638,642}

The nodules have a similar appearance to the cellular and fibrous patterns seen in a dermatofibroma. There are histiocytes, foam cells, and spindle-shaped cells, sometimes arranged in a storiform pattern,⁶⁰³ this is particularly the case in older, nodular lesions.⁶⁴⁷ The cells are embedded in a delicate fibrocollagenous matrix. Touton cells may be present. There are usually no other inflammatory cells. Fat and hemosiderin can be demonstrated in the histiocytes with special stains.

Cells express vimentin, CD68, HAM-56, and factor XIIIa but not CD34, CD1a, or S100 protein. Lack of factor XIIIa expression has been found in some cases.⁶⁴¹ Variable staining occurs for Mac387, lysozyme, α_1 -antitrypsin, and smooth muscle actin.⁶⁰³

Electron microscopy

Ultrastructural examination demonstrates an absence of Birbeck granules.^{603,640} Other electron microscopic features include cytoplasmic inclusions with laminated or highly complex structures^{603,640,648} and lipid

phagocytosis.⁶³⁸ Torres and associates identified dense granules, some comma-shaped and some with electron-lucent centers, in a case of progressive nodular histiocytosis.⁶⁴⁶

Differential diagnosis

Progressive nodular histiocytosis has such a close microscopic resemblance to JXG (particularly to those forms with a spindle cell component) that these are now widely considered variants of the same disorder.^{603,649} The microscopic findings can also closely resemble those of dermatofibroma. Ordinarily, the clinical presentation of a progressive eruption of papules and nodules is distinctly different from that of dermatofibroma. However, Zelger and coworkers described a solitary variant of spindle cell xanthogranuloma (progressive nodular histiocytosis) that is diagnostically more problematic. Microscopic differences from dermatofibroma reported in these solitary tumors include a lack of overlying epidermal hyperplasia or of sclerotic collagen, a particularly prominent xanthogranulomatous reaction and peripheral lymphocytic infiltrate, and reliable reactivity for macrophage markers.⁶⁰³ However, dermatofibromas can be virtually identical, and it remains to be seen if the concept of a solitary version of progressive nodular histiocytosis will become widely accepted. The complex inclusion bodies seen on ultrastructural examination of lesions of progressive nodular histiocytosis are similar to those of reticulohistiocytoma, but in other respects the clinical and microscopic features differ significantly from both solitary reticulohistiocytoma and multicentric reticulohistiocytosis (see later).

XANTHOMA DISSEMINATUM

Xanthoma disseminatum is a rare normolipemic histiocytic proliferation of dendrocyte origin. It presents with papules, nodules, and plaques that have a predilection for flexural areas, the proximal parts of the extremities, and the trunk. The face is sometimes involved.⁶⁵⁰ The lesions are initially reddish-brown in color but become yellow with time.⁵²⁶ Mucosal lesions and transitory diabetes insipidus are present in approximately 40% of affected individuals.⁶⁵¹⁻⁶⁵⁴ Involvement of the pituitary stalk can also result in hyperprolactinemia and hypopituitarism.⁶⁵⁵ Skeletal involvement has also been recorded.⁶⁵⁶ Waldenström's macroglobulinemia was present in one case.⁶⁵⁷ The condition runs a chronic but usually benign course. Spontaneous resolution has been reported, but with residual scarring, anetoderma, and/or systemic effects (e.g., persistent diabetes insipidus).⁶⁵⁸ Widespread systemic involvement and death have been reported.^{659,660}

Xanthoma disseminatum appears to be a clinically distinctive disorder in which there is a primary proliferation of histiocytes with subsequent accumulation of lipid.^{661,662} It may represent an evolutionary form of generalized eruptive histiocytoma (see later) and as such be part of the spectrum of dendritic disorders related to (juvenile) xanthogranuloma.

Treatment with CO₂ laser therapy has been successful.⁶⁶³ Azathioprine and corticosteroids were used in a child with xanthoma disseminatum who had hepatic involvement.⁶⁶⁴ In another patient, a combination of three lipid-lowering agents was used.⁶⁶⁵

Histiocytes predominate in the early stages, but in established lesions there are histiocytes, foam cells, spindle cells, Touton cells, and a moderate number of chronic inflammatory cells (Fig. 40.19).⁵²⁴ There may be phagocytosis of elastic fibers and sometimes of collagen by macrophages.⁶⁶¹ Siderosis is often observed, and this is quite prominent in the rare variant known as **xanthosiderohistiocytosis**.⁶⁶⁶

Immunohistochemical characterization of the cells has shown HLA-DR positivity but no staining for S100 protein, CD4, or CD1a.⁶⁶⁷ The cells express CD68, Ki-M1p, CD14, CD11b, CD11c, and factor XIIIa,^{665,668,669} although factor XIIIa was negative in a recent case.⁶⁷⁰ There is variable staining with Mac387.

Figure 40.19 Xanthoma disseminatum. Histiocytes with ovoid, vesicular nuclei and scalloped borders predominate, but scattered inflammatory cells, including eosinophils, can also be identified. (H&E)

Electron microscopy

The cells are similar to those seen in papular xanthoma and JXG, but the plasma membranes of the foamy cells show many microvilli.⁵²⁴ There are no Birbeck granules.

Differential diagnosis

Early xanthoma disseminatum can closely resemble other forms of non-Langerhans cell histiocytosis. Examples with numerous Touton giant cells can be confused with JXG. Immunohistochemistry would ordinarily be of little help in distinguishing between these two conditions. Zelger and coworkers considered in detail the morphologic and immunohistochemical differences between xanthoma disseminatum and Langerhans cell histiocytosis. In contrast to xanthoma disseminatum, lesions of Langerhans cell histiocytosis tend to have a more diffuse, band-like infiltrate with epidermal infiltration. Langerhans cells have higher nuclear-to-cytoplasmic ratios than do the cells of xanthoma disseminatum and possess reniform nuclei.⁶⁶⁸ In addition, the cells of Langerhans cell histiocytosis are positive for S100 and CD1a and stain strongly with peanut agglutinin.^{652,668}

ERDHEIM-CHESTER DISEASE

Erdheim-Chester disease is a rare, disseminated form of non-Langerhans cell histiocytosis. The age of presentation is typically in the fifth decade of life.⁶⁷¹ It is primarily a disease of long bones producing patchy medullary sclerosis on radiographs, with sparing of the epiphyses.^{641,672} Extraskeletal manifestations can occur in almost every organ, including the lungs, pericardium, hypothalamus/pituitary, the orbit, and retroperitoneum.

The skin is affected in approximately 30% of cases.⁶⁷¹ Cutaneous lesions include diffuse dermal nodules similar to xanthoma disseminatum,⁶⁷³ xanthelasmas, subcutaneous nodules, intertrigo-like lesions,⁶⁷¹ pretibial dermatopathy, and pigmented patches on the lips and oral mucosa. Verruca plana-like papules, infiltrated by foamy cells, may also be present.⁶⁷²

Ancillary techniques for molecular diagnosis have not yet been established; a t(12;15;20) balanced chromosomal translocation has been reported in one patient with osseous Erdheim-Chester disease.⁶⁷⁴

Histopathology

Erdheim–Chester disease is basically a xanthomatous process, but it has been considered here, perhaps arbitrarily, because it is primarily an infiltrate of histiocytes of non-Langerhans cell type. The variably lipidized histiocytes involve the dermis, often with extension into the subcutis. Sometimes there are Touton giant cells, but multinucleate cells may be completely absent. There is variable fibrosis; sometimes lesions are quite sclerotic. The cells are CD68⁺, factor XIIIa⁺, CD1a⁺, and S100⁺. In a recent report of Erdheim–Chester disease with cutaneous involvement, the histiocytes were strongly CD163⁺, weakly CD68⁺, and showed S100 positivity only in the most superficial portion of the infiltrate.⁶⁷⁵

Differential diagnosis

The microscopic differential diagnosis has been recently reviewed by Volpicelli *et al.*⁶⁷⁵ JXG can have a close resemblance to lesions of Erdheim–Chester disease, particularly in older lesions with fibrosis, and the immunohistochemical findings are quite similar. The differences are largely clinical and radiologic, wherein Erdheim–Chester disease is most likely to show symmetrical, sclerotic bony involvement. Rosai–Dorfman disease shows emperipolesis by histiocytes that are strongly S100 positive. Xanthoma disseminatum lesions are again quite similar to Erdheim–Chester disease histopathologically, and the differences are largely clinical, with the former primarily showing mucocutaneous involvement and only rare bony changes. Necrobiotic xanthogranuloma differs by its microscopic findings of necrobiosis, with cholesterol clefts, surrounding granulomas, and an association with paraproteinemia. The histiocytes of true xanthomas have a similar immunophenotype to those of Erdheim–Chester disease, and fibrosis can sometimes be seen, particularly in tuberous xanthomas, but the clinical presentations that accompany dyslipidemia are quite different. Langerhans cell histiocytosis lesions feature histiocytes with folded or reniform nuclei that are generally S100, CD1a, and langerin positive, although variability of expression of these antigens could create diagnostic problems in isolated circumstances.⁶⁷⁵

SEA-BLUE HISTIOCYTE SYNDROME

The sea-blue histiocyte syndrome (OMIM 269600) is a rare, inherited systemic histiocytosis characterized by histiocytes with deep azure blue granules in the cytoplasm on Giemsa, toluidine blue, and May–Gruenwald staining.^{503,641} Secondary forms, associated with storage diseases such as Niemann–Pick disease (type B), and other diseases have now been reported.⁵⁰³ Commonly involved organs are bone marrow, liver, and spleen. Cutaneous lesions are rare and found in only a few patients.⁶⁴¹ They consist of nodular lesions and brown pigmented macules, both on the face. When disseminated lesions are present, it may lead to death.

A partial deficiency of sphingomyelinase is a possible cause.⁶⁴¹ Two reports have linked the disease to the *APOE* gene at 19q13.2, which is involved in lipid metabolism (see OMIM log).

Histopathology

Cutaneous lesions consist of dermal infiltrates of large monomorphous histiocytes with cytoplasmic vacuoles and granules.^{503,642} The granules are yellow-brown on hematoxylin and eosin (H&E) and dark blue with toluidine blue or Giemsa staining. They show yellow autofluorescence, and they display birefringence under polarized light.

The histiocytes are CD68⁺ and S100⁺. They do not appear to have been tested for CD1a or factor XIIIa.⁶⁴¹

GENERALIZED ERUPTIVE HISTIOCYTOMA

Generalized eruptive histiocytoma is a rare histiocytosis, characterized clinically by the development of recurrent crops of hundreds of small reddish papules that are distributed symmetrically on the trunk and on the extensor surfaces of the extremities.^{635,676–680} Approximately 30 cases have been reported. It has been documented in children as well as in adults.^{676,677,681,682} Lesions usually subside spontaneously, leaving macular hyperpigmentation or no residual features. It has been suggested that regression involves apoptosis of the infiltrating histiocytes.⁶⁸³ In one case, resolution followed exanthem subitum (roseola infantum).⁶⁸⁴ Two cases have been associated with acute leukemia.⁶⁸⁵ Evolution into xanthoma disseminatum has been reported – further evidence of the close interrelationship of the various non-Langerhans cell histiocytoses, which appear to form part of a continuous spectrum.^{686,687}

Although often thought to be a self-limiting disease, recurring crops of lesions continued for 12 years in one patient. This necessitated treatment, which was successful using a combination of corticosteroids, hydroxychloroquine, and thalidomide.⁶⁸⁸

Histopathology^{678,679}

There is an infiltrate of histiocyte-like cells, often spindle shaped, in the upper and mid dermis. Sometimes the cells are arranged in nests around blood vessels. They have pale cytoplasm and an oval nucleus. No lipid, iron, or PAS-positive material is demonstrable in the cytoplasm. A few lymphocytes, and sometimes fibroblasts, are intermingled, but there are usually no giant cells or xanthoma cells (Fig. 40.20).⁶⁸⁶ However, giant cells have been reported.⁶⁸⁷ The histiocytes are negative for S100 protein and CD1a but are positive for CD11b, CD14, CD36, factor XIIIa, CD68, and MS-1 protein.^{677,686,687,690} This latter antigen has been found in all of the non-Langerhans cell histiocytoses tested. It is specific for sinusoidal endothelial cells and dendritic perivascular macrophages.⁵⁰⁷ The cells in generalized eruptive histiocytoma show only patchy positivity for Mac387.⁶⁸⁹ A case with some S100⁺ cells has been regarded as an indeterminate cell variant.⁶⁹¹

Figure 40.20 Generalized eruptive histiocytoma. Numerous histiocytes can be seen, which are not spindle-shaped in this example. Scattered lymphocytes are also identified. (H&E)

Electron microscopy

There are many dense bodies, some with myelin laminations, in the cytoplasm.⁶⁷⁸ There are also occasional comma-shaped bodies and lipid droplets but no Birbeck granules.^{677,679}

Differential diagnosis

The microscopic features are similar to those of early lesions of JXG. Rare reports of transition to xanthoma disseminatum also suggest a close relationship to that condition. However, in contrast to these disorders, foam cell and giant cell formation are not usually features of generalized eruptive histiocytoma. Lesions of reticulohistiocytosis differ from those of generalized eruptive histiocytoma by possessing cells with 'ground glass' cytoplasm and more frequent multinucleated cells; the latter are particularly prominent in older lesions. Benign cephalic histiocytosis and a case reported as 'benign non-X histiocytosis'⁶⁹² have features on light microscopy that are similar to those of generalized eruptive histiocytoma, but they differ clinically and ultrastructurally.⁶⁷⁷ As mentioned previously, many of the non-Langerhans histiocytoses of dendritic origin may be different expressions of the same histiocytosis.⁶³⁵

PROGRESSIVE MUCINOUS HISTIOCYTOSIS

Progressive mucinous histiocytosis (OMIM 142630) – a very rare, non-Langerhans cell histiocytosis of childhood – was first described by Bork and Hoede in 1988.^{693,694} Sporadic cases in adults have since been reported.⁶⁹⁵ Fewer than 20 patients have been described. Until recently, all patients had been female, but the first male patient has now been reported.⁶⁹⁶ It is characterized by a progressive eruption of skin-colored to red-brown papules with a predilection for the face and extremities. It appears to have an autosomal dominant mode of inheritance.⁶⁹⁷ The gene responsible has not been elucidated.

Histopathology

There is a dermal infiltrate of epithelioid and spindle-shaped histiocytes, with the latter predominating in older lesions.⁶⁹⁸ There is marked metachromasia of these cells with toluidine blue.⁶⁴¹ There are rare giant cells but no foam cells.⁶⁹⁹ The cells are set in a collagenous stroma containing abundant mucin (Fig. 40.21). Mast cells can be quite numerous.⁷⁰⁰ There is some variability in immunohistochemical staining. The cells stain for HAM-56, lysozyme, and vimentin but not for CD1a, S100 protein, CD34, or Mac387.^{695,700} CD68 and factor XIIIa have been variously reported to be negative and positive. In a recent case, the histiocytes were factor XIIIa⁺ and only a few were CD68⁺, but CD31 staining was positive (CD31 stains circulating monocytes and macrophages as well as endothelial cells).⁶⁹⁶

Electron microscopy

Zebra and myeloid bodies are quite numerous in the cytoplasm of the histiocytes. This suggests a lysosomal storage phenomenon. Birbeck granules are absent. Electron microscopy is considered a key to the diagnosis of these lesions.⁷⁰¹

MULTICENTRIC RETICULOHISTIOCYTOSIS

Multicentric reticulohistiocytosis is an uncommon normolipemic histiocytosis that is characterized by the presence of an extensive papulonodular cutaneous eruption and a severe, sometimes destructive, arthropathy, the onset of which may precede, follow, or accompany the eruption of skin lesions.^{702–706} The interphalangeal joints of the hands are usually affected. Uncommonly, articular damage is minimal.⁷⁰⁷ Oral, nasal, and pharyngeal mucosae are often involved. There are isolated reports of infiltrates in lymph nodes, lungs,^{708,709} bone marrow,

Figure 40.21 Mucinous histiocytosis. (A) There are epithelioid and spindle cell histiocytes set in a collagenous and mucinous stroma. (B) This area is at the interface between the mucinous and more cellular areas seen in (A). (H&E)

the skull,⁷¹⁰ endocardium, stomach, salivary gland,⁷¹¹ and perirenal fat. Xanthelasma of the eyelids are also common.⁷⁰³ More than 200 cases of this condition have now been described. A retrospective study of 96 of these patients was reported in 2001.⁷¹²

The cutaneous lesions, which preferentially involve the face and distal parts of the upper extremities, are multiple brown-yellow papules and nodules measuring 0.3–2 cm in diameter. Rare presentations have included the presence of lesions resembling neurofibromatosis⁷¹³ or dermatomyositis⁷¹⁴ and the localization of lesions to the sites of healed herpes zoster.⁷¹⁵ Onset of the disease is usually in middle life, and there is a predilection for females. Childhood onset is rare.^{716,717} The clinical course is variable, with eventual spontaneous regression of the skin lesions after 5–10 years or more.⁷¹⁸ There may be residual joint impairment as a consequence of macrophages in synovial fluid differentiating into osteoclasts and causing bone resorption.⁷¹⁹ Malignancies of various types may develop in up to 30% of cases.^{704,720–723} Myelofibrosis has also been associated with this condition.⁷²⁴ Systemic vasculitis is rarely associated with multicentric reticulohistiocytosis.

Because of the rarity of the disease, no consistent approach to treatment has emerged.⁷²⁵ A combination of an oral alkylating agent with prednisone has been used with variable success.⁷²⁵ Because immunohistochemical staining of the infiltrate in this condition has

demonstrated the presence of histiocytes of a monocyte–macrophage lineage and an abundance of cytokines, including TNF- α , a trial of etanercept (an anti-TNF agent) has been used with prednisone.⁷²⁶ Skin lesions and synovitis completely resolved with this regimen.⁷²⁶ There is a single case report of success with alendronate.⁵⁰³

A related entity is **diffuse (multiple) cutaneous reticulohistiocytosis**, in which multiple cutaneous lesions, identical histologically to those seen in multicentric reticulohistiocytosis, develop in the absence of arthritis or systemic lesions.^{727–729} The terms ‘reticulohistiocytoma’ and ‘reticulohistiocytic granuloma’ have been used for solitary cutaneous lesions of similar histology (see later).

Histopathology^{702,711,730}

There is a circumscribed non-encapsulated dermal and synovial infiltrate of mononuclear and multinucleate histiocytes with an eosinophilic, finely granular ‘ground-glass’ cytoplasm. The nuclei of these cells feature sharply delineated nuclear membranes and prominent nucleoli; occasional mitoses can be identified. The hallmark of the disease is the presence of the multinucleate cells, which measure 50 μ m or more in diameter (Fig. 40.22). They have 3–10 or more nuclei, which may be placed haphazardly, along the periphery, or clustered in the center of the giant cell. Some giant cells may have foamy cytoplasm at the periphery. Phagocytosis of nuclear debris is uncommon. Transition from mononucleate to multinucleate forms can be seen.⁷³¹ Giant cells may be sparse in early lesions. The cytoplasm of the histiocytes contains PAS-positive diastase-resistant material, which usually stains with Sudan black as well.^{702,732} Reticulin fibers can be demonstrated around individual cells.

Immunohistochemistry shows that the histiocytic cells express CD45, CD68, CD11b, vimentin, and HAM-56 but not S100 protein, Mac387, CD34, or CD1a.^{712,727,733,734} There are reports of the cells expressing factor XIIIa, but in one of these cases the cells also stained for S100 protein, suggesting an unusual lineage.⁷³⁵

In addition to the histiocytes, small numbers of lymphocytes are scattered through the infiltrate. There may be some perivascular cuffing by lymphocytes in early lesions.⁵²⁴ The walls of small blood vessels sometimes show ‘onion-skin’ thickening.⁷⁰³

Epidermal changes are variable. There is sometimes thinning of the epidermis overlying the lesion, with loss of rete ridges; ulceration is uncommon. Usually, there is a narrow grenz zone of uninvolved collagen that separates the undersurface of the epidermis from the tumor nodule below.

Figure 40.22 Multicentric reticulohistiocytosis. The characteristic multinucleate giant cells are scattered through the collagen of the dermis. (H&E)

Electron microscopy

The cytoplasm of the histiocytes is rich in organelles. A characteristic feature is the presence of innumerable rounded dense bodies with the morphological structure of lysosomes.⁷³¹ Lipid vacuoles are sometimes present, but there are no Birbeck granules.⁷¹¹ Elastin and collagen in various stages of degeneration may be seen in the cytoplasm of some of the giant cells.^{736,737} Intra- and extracytoplasmic long spacing collagen (type VI) has been reported in one case.⁷³⁸

RETICULOHISTIOCYTOMA

Reticulohistiocytomas (reticulohistiocytic granulomas) are nodular lesions 0.5–2 cm in diameter, with similar histology to the lesions of multicentric reticulohistiocytosis but without associated arthritis or systemic lesions.^{705,739} They are usually solitary, but several may be present.^{739–743} There is a predilection for the head and neck, but they may occur anywhere on the skin. Paraproteinemia accompanied several cutaneous nodules in one reported case.⁷⁴⁰ In a report of 44 cases from the Armed Forces Institute of Pathology (AFIP), the term ‘solitary epithelioid histiocytoma’ was suggested as the preferable designation for this tumor.⁷⁴²

Histopathology⁷³⁹

There is a circumscribed dermal nodule, often with overlying epidermal thinning. As with multicentric reticulohistiocytosis, there is an irregular admixture of oncocyctic mononuclear histiocytes, multinucleate giant cells with a ‘ground glass’ appearance, and inflammatory cells (Fig. 40.23). Phagocytosis of leukocytes is sometimes seen. A few Touton giant cells may be present, and these may contain lipid. Reticulin fibers are increased and surround individual cells.

There is usually more of a neutrophilic infiltrate than in multicentric reticulohistiocytosis, and a further point of distinction is the greater propensity for the stroma in reticulohistiocytoma to have many spindle-shaped cells and for there to be xanthomatized cells.⁷³⁴

Immunohistochemistry suggests a dendritic cell lineage with staining for factor XIIIa, CD68, HAM-56, lysozyme, α_1 -antitrypsin, CD11b, and CD14. The cells are negative for CD1a, CD34, and smooth muscle actin.^{734,743,744} Positive staining for S100 protein has been

Figure 40.23 Solitary reticulohistiocytoma composed of multinucleate giant cells, histiocytes, and lymphocytes. Nuclei have distinct chromatin rims and prominent nucleoli. The ‘ground glass’ cytoplasm of these cells is apparent. (H&E)

reported in several cases, but it is usually negative.^{607,745} In the series reported from the AFIP (discussed previously), the epithelioid histiocytes were positive for CD163, CD68, lysozyme (variably), and vimentin.⁷⁴²

Differential diagnosis

The cytologic features of the cells of reticulohistiocytoma, with their characteristic 'ground glass' cytoplasm, ordinarily permit ready distinction from JXG, in which lipidized cells and Touton giant cells predominate. Similarly, distinction from other conditions characterized by lipidized cells, including xanthomas, dermatofibroma, and lepromatous leprosy, is usually not difficult. Confusion with Langerhans cell histiocytosis is possible, particularly in those cases of reticulohistiocytoma that are S100⁺. However, the nuclei of reticulohistiocytoma cells lack the reniform features of Langerhans cell histiocytosis. In one S100⁺ case of reticulohistiocytoma, no Birbeck granules were found ultrastructurally.⁷⁴⁵

FAMILIAL HISTIOCYTIC DERMATOARTHRITIS

Familial histiocytic dermatoarthritis (OMIM 142730) is an exceedingly rare disorder that presents in childhood or adolescence as a papulonodular eruption on the face and limbs associated with a symmetrical destructive arthritis and ocular lesions. A closely related entity is the autosomal recessive dermo-chondro-corneal dystrophy (OMIM 221800) reported in the French literature.⁷⁴⁶ The gene responsible has not yet been identified.

Histopathology

There is a dermal infiltrate of mononuclear histiocytes admixed with some lymphocytes and plasma cells. There is no stored lipid or PAS-positive cytoplasmic material. Fibrosis is conspicuous in older lesions. Two cases have been reported in which multinucleate histiocytes were present. PAS-positive material was present in the cytoplasm. PAS-positive, diastase-sensitive material, representing glycogen, is present in the cytoplasm.⁷⁴⁶ The authors suggested that these two cases had features overlapping with both familial histiocytic dermatoarthritis and multicentric reticulohistiocytosis, which probably form part of a spectrum of dermatoarthritis.⁷⁴⁶

Differential diagnosis

Familial histiocytic dermatoarthritis and multicentric reticulohistiocytosis are both dermatoarthritis that can include giant cells, PAS-positive intracytoplasmic material, and pleomorphic inclusions on ultrastructural examination. However, a family history, early onset of disease, and ocular abnormalities are features not associated with multicentric reticulohistiocytosis. In contrast to familial histiocytic dermatoarthritis, the PAS-positive cytoplasmic material in multicentric reticulohistiocytosis is not glycogen, and it is therefore resistant to diastase. Multinucleated giant cells are not invariably present in multicentric reticulohistiocytosis (this is particularly the case in early lesions), and the classic 'ground glass' cytoplasm and nuclear features of the cells in that disorder have not been reported to date in cases of familial histiocytic dermatoarthritis.

NECROBIOTIC XANTHOGRANULOMA

Necrobiotic xanthogranuloma, a rare chronic disorder, was first delineated by Kossard and Winkelmann in 1980.^{747,748} It is characterized by the presence of multiple sharply demarcated nodules and large indurated plaques.⁷⁴⁹ Sometimes only papulonodules are present.⁷⁵⁰ A solitary variant has been described.^{751,752} Lesions are violaceous to red, with a partly xanthomatous hue. Central atrophy, ulceration, and

telangiectasia may develop. There is a predilection for the periorbital area, but other areas of the face, as well as the trunk and limbs, are often involved.^{753,754} It has also been reported in a burn scar.⁷⁵⁵

Paraproteinemia has been present in nearly all the reported cases.⁷⁵⁶⁻⁷⁶¹ IgG monoclonal paraprotein is most common, but rarely IgA has been detected. Recently, a case of necrobiotic xanthogranuloma was associated with IgM monoclonal gammopathy in the setting of macroglobulinemia of Waldenström.⁷⁶² Two monoclonal paraproteins were present in one case.⁷⁶³ Other less frequent findings include leukopenia, bone marrow plasmacytosis, non-Hodgkin's lymphoma,⁷⁶⁴ small lymphocytic lymphoma in a patient with Sjögren's syndrome,⁷⁶⁵ hypocomplementemia,⁷⁶⁶ and, occasionally, hyperlipidemia. Normolipemic plane xanthoma has been reported in association with necrobiotic xanthogranuloma, suggesting that the two conditions are part of a spectrum.^{760,767} It has also developed within linear morphea.⁷⁶⁸ Ophthalmic complications are common and include scleritis, episcleritis, and keratitis. Cardiac and laryngeal involvement has been recorded.^{769,770} Skeletal muscle has been involved without overlying dermal disease.⁷⁷¹ The clinical course is chronic and often progressive.⁷⁷²

Necrobiotic xanthogranuloma has been regarded as a paraneoplastic phenomenon, but recent findings raise the possibility that it is an infectious disease in immunocompromised patients, particularly those with multiple myeloma.⁷⁷³ This theory results from the finding of *Borrelia* organisms in six of seven cases using focus-floating microscopy, a technique in which sections are simultaneously scanned both horizontally and vertically.⁷⁷³ As the authors point out, it is possible that new strains of *Borrelia* or related spirochetes, not yet properly characterized, could be involved in the etiology.⁷⁷³

Treatment of necrobiotic xanthogranuloma is difficult due to the chronic and progressive nature of the disease. Therapy is usually directed at the underlying hematological disorder. Melphalan, chlorambucil, methotrexate, cyclophosphamide, plasmapheresis, IFN- α -2b, prednisone, and local corticosteroid injections have all been used.⁷⁶¹ Thalidomide has also been used to treat this disease.⁷⁷⁴

Histopathology⁷⁷⁵

The distinctive changes are found in both the dermis and the subcutis, and they consist of broad zones of hyaline necrobiosis and granulomatous foci composed of histiocytes, foam cells, and multinucleate giant cells (Fig. 40.24). The giant cells are of both Touton and foreign body type; the latter often have bizarre features with irregular size, shape, and distribution of the nuclei. Asteroid bodies and other inclusions are sometimes present.⁷⁷⁶ The multinucleate cells may be present in the granulomas and dispersed near the zones of necrobiosis. Sometimes the Touton cells are prominent in the subcutis ('Touton cell panniculitis'). Giant cells are occasionally quite sparse.⁷⁷⁷ Blood vessels may be secondarily involved in the granulomatous process.

The amount of xanthomatization is variable, and sometimes the foam cell population is small.⁷⁷⁷ Aggregates of histiocytes may extend into the papillary dermis, and there may be ulceration. Other less constant changes include the presence of cholesterol clefts,⁷⁷⁸ rarely with surrounding palisaded granuloma formation; the presence of lymphoid nodules, sometimes with germinal centers; and plasma cell collections. Eosinophils are rare. Transepithelial elimination of cholesterol crystals and cellular debris has also been documented.⁷⁵⁷

Despite this rather characteristic constellation of microscopic changes, variants have been described that are either lipid and giant cell-poor⁷⁷⁷ or 'non-necrobiotic' (though with foam cells, extracellular lipid, and cholesterol clefts).^{765,777,779}

Histochemical findings include scant mucin in areas of necrobiosis; sparse or absent elastic fibers; focal lipid droplets in giant cells and histiocytes and in some areas of necrobiosis; and PAS-positive, diastase-resistant granules in giant cells. The histiocytes stain with Mac387. Scattered cells are CD68⁺, whereas only isolated cells stain for S100

Figure 40.24 (A) Necrobiotic xanthogranuloma. A zone of necrobiosis is surrounded by multinucleate giant cells and some histiocytes. **(B)** Cholesterol clefts and giant cells are present. (H&E)

protein.⁷⁷² In one report, most dermal cells were CD68⁺, and there was focal positivity for CD10.⁷⁷⁹

Electron microscopy has not contributed any useful further information.

Differential diagnosis

The lesion that has microscopic features most similar to necrobiotic xanthogranuloma is necrobiosis lipoidica. In addition to the necrobiosis common to both lesions, necrobiosis lipoidica can also rarely feature cholesterol clefts.⁷⁷⁸ However, in general, necrobiotic xanthogranuloma is a more cellular process and has more atypical and prominent giant cells than necrobiosis lipoidica. In addition, necrobiotic xanthogranuloma is more likely to feature Touton-type giant cells and granulomatous involvement of the walls of muscular vessels with thrombosis.⁷⁷⁸

ORBITAL XANTHOGRANULOMA

Orbital xanthogranuloma is a rare cutaneous disease, first reported in 1991, and characterized by bilateral, rather symmetrical infiltrates around the eyes of adult patients.^{780–782} As such, it has some clinical

resemblance to necrobiotic xanthogranuloma (discussed previously).⁷⁸³ There is no systemic involvement, but associated clinical diseases have included adult-onset asthma and hematological abnormalities.⁷⁸² Lesions enlarge very slowly over many years.

Histopathology

There is a diffuse dermal and subcutaneous infiltrate of histiocytes that range from spindle-shaped cells to oval cells and to large cells with foamy cytoplasm.⁷⁸² They infiltrate the dermis and subcutis. Large cells with foamy cytoplasm and multiple nuclei with some resemblance to Touton cells are present. A variable admixture of lymphocytes, plasma cells, and eosinophils may be present.⁷⁸² Focal, mild necrobiosis (collagenolysis) has been noted, indicating the close relationship of this disease to necrobiotic xanthogranuloma.⁷⁸²

CUTANEOUS ATYPICAL HISTIOCYTOSIS

Only a few cases of cutaneous atypical histiocytosis have been reported.^{784,785} It is characterized clinically by the presence of one or more nodular lesions resembling cutaneous lymphoma. There has been a good response to various modes of treatment in the cases reported so far. The status of this entity is doubtful.

Histopathology

There is a monomorphous infiltrate of medium-sized histiocytoid cells with occasional cytoplasmic vacuoles and scattered mitoses.

Electron microscopy

The distinctive feature is the presence in the cells of giant multivesicular bodies and pleomorphic granules.

INDETERMINATE CELL HISTIOCYTOSIS (INDETERMINATE CELL TUMOR)

Indeterminate cells are a class of dendritic cells found in the dermis. They display similar histological and antigenic features to Langerhans cells: both express S100 protein and CD1a surface antigens.⁷⁸⁶ They differ by lacking Birbeck granules and by possessing some histiocytic markers such as CD68. There is controversy regarding this diagnosis and whether it represents overlap of Langerhans cell and non-Langerhans cell histiocytosis or simply a variant of non-Langerhans cell histiocytosis, including Rosai–Dorfman disease.⁷⁸⁷

Only a few cases of indeterminate cell histiocytosis have been reported.⁶⁴¹ They usually present as multiple reddish-brown to yellowish papules.^{788–790} A solitary congenital variant⁷⁸⁶ and a solitary acquired lesion on the mucosa of the glans penis have also been reported.⁷⁹¹ A large series of 18 patients was described in 2005.⁷⁸⁷ The authors of this series speculated that this disease might represent various macrophage disorders identified at various time points in the inflammatory response.⁷⁸⁷ Cases that progressed to leukemia have been reported,^{792,793} and there has been a case associated with progressive follicular lymphoma.⁷⁹⁴ A case of indeterminate cell sarcoma has been reported.⁷⁹⁵ Vinblastine has been used to treat aggressive variants.⁷⁹⁶ Partial remission has been obtained using ultraviolet-B phototherapy.⁷⁹⁷ Electron beam therapy is another option.⁷⁹⁸

Histopathology

The tumor is composed of a monomorphous infiltrate of mononuclear, and occasionally multinucleate, histiocytes intermingled with clusters of lymphocytes. The cytoplasm is pale, and the nucleus is often clefted.⁷⁸⁶ In one case, the cells were spindle-shaped with interspersed epithelioid histiocytes.⁷⁹⁰

The cells express S100 protein, CD1a, CD68, and HAM-56.^{786,788,791} Although indeterminate cells are said to be factor XIIIa⁵⁰², several reports have mentioned positive staining with this marker in this tumor.^{789,790} CD34 is negative.⁷⁹⁰ A case that was S100⁺ has been reported.⁷⁹⁹ A key diagnostic feature – the absence of Birbeck granules – formerly could only be determined using electron microscopy. However, studies have indicated that the immunohistochemical stain langerin (CD207) can be used as a surrogate for this ultrastructural feature, and an absence of langerin in this context would provide strong diagnostic support for the diagnosis of indeterminate cell histiocytosis.⁷⁹³

ROSAI–DORFMAN DISEASE

The eponymous designation Rosai–Dorfman disease⁸⁰⁰ is more appropriate than ‘sinus histiocytosis with massive lymphadenopathy’ because it is now recognized that in some instances, extranodal lesions, including lesions in the skin, may be the sole manifestation of this condition.^{801–815} Cutaneous Rosai–Dorfman disease appears to be a distinct entity with different age and race distributions from cases with nodal disease.⁸¹⁶ It also has a wider histopathological spectrum.⁸¹⁷ The typical presentation is with painless cervical lymphadenopathy accompanied by fever, anemia, an elevated erythrocyte sedimentation rate, and hypergammaglobulinemia, which has been polyclonal in all but one case.^{818–820} Any age may be affected, but 80% of cases develop in the first two decades of life. Extranodal lesions occur in almost one-third of cases, and the skin has been involved in more than 10% of the many cases now reported.^{801,819} Purely cutaneous disease is uncommon; more than 100 cases have now been reported, most in the past few years.^{817,821,822}

Cutaneous lesions, which are usually multiple, have been varied in their clinical appearance.⁸⁰¹ There may be nodules up to 4 cm or more in diameter,^{823,824} papules that are erythematous or xanthomatous,⁸⁰¹ plaques, pustules, acneiform lesions,⁸²⁵ pigmented macules,⁸⁰² and even a transient panniculitis.⁸²⁶ In one case, the presentation mimicked a vasculitis.⁸²⁷ The eyelids and the malar regions are the sites of predilection.^{802,828} In the study of purely cutaneous disease by Brenn and colleagues, there was no site predilection.⁸²¹ Furthermore, 13 of the 22 cases had multifocal disease. Only 4 of the 21 patients with pure cutaneous disease reported from Taiwan had multifocal involvement.⁸²⁹

The disease usually runs a benign, albeit protracted, clinical course, sometimes with significant morbidity.⁸¹⁹ Death may sometimes result from infiltration of organs or from immunological disturbances.^{802,830–832} The lesions resolved, regardless of the treatment given, in 6 of 13 patients, for whom follow-up data were available, in the series of 22 cases, referred to previously.⁸²¹ It is a polyclonal disorder of macrophage origin.⁵⁰² Its association with coexisting Langerhans cell histiocytosis may represent a reactive proliferation of Langerhans cells within a lesion of Rosai–Dorfman disease.^{822,833} Its association with other histiocytoses may have implications for its pathogenesis.⁸¹⁷ A case of cutaneous Rosai–Dorfman disease followed pneumococcal vaccination, suggesting vaccine-induced immune stimulation as a possible triggering factor.⁸³⁴ The occurrence of other malignancies is so rare that it may be incidental.⁸³⁵ HHV-6 has been isolated from a skin lesion in 1 case.⁸³⁶ Both HHV-6 and HHV-8 were not detected in a further 3 cases.⁸³⁷ More recently, large numbers of cells positive for parvovirus B19 were found by immunohistochemistry in 4 cases, suggesting that this may be the etiological agent.⁸³⁸ An association between cutaneous Rosai–Dorfman disease and long-standing Crohn’s disease has been reported, suggesting a pathogenetic link between these two disorders.⁸³⁹

When anatomically feasible, complete excision is the treatment of choice for persistent or recurrent extranodal disease.^{822,840} When

surgical margins are involved, local recurrence is likely. Radiotherapy has shown limited efficacy, whereas chemotherapy is generally ineffective.⁸⁴⁰ Isotretinoin has been used to treat this condition,^{828,841} whereas high-dose thalidomide has been used for extensive cutaneous disease.⁸²⁷ Corticosteroids were used in another case.⁸⁴² Dapsone has been suggested for cases with a neutrophilic predominance.⁸⁴³ The tyrosine kinase inhibitor imatinib was used successfully to treat systemic disease.⁵²²

Histopathology⁸⁰¹

The pathological changes in the lymph nodes are characteristic and include expansion of the sinuses by large foamy histiocytes admixed with plasma cells. Cutaneous lesions show a dense dermal infiltrate of large polygonal histiocytes admixed with inflammatory cells. There may be a prominent infiltrate of eosinophils.⁸⁴⁴ The histiocytes have abundant, lightly eosinophilic cytoplasm and vesicular nuclei.⁸⁰¹ These cells show variable emperipolesis (intracytoplasmic inflammatory cells) (Fig. 40.25).^{821,829} Scattered multinucleate cells and Touton cells and collections of neutrophils may be present.^{817,818} Plasma cells are invariably present, and sometimes they contain prominent Russell bodies. Nodular lymphoid aggregates may be conspicuous.

Other features that may be present include xanthoma cells,^{822,845} fibrosis, increased vascularity, and focal necrosis.⁸⁰¹ In some lesions, there is a markedly sclerotic, often storiform, fibrous stromal response.⁸²¹ Rarely, the pattern is that of an inflammatory pseudotumor.⁸⁴⁶ Histiocytes are often present in dilated lymphatics in the dermis.⁸⁰⁸ A mixed septal and lobular panniculitis with some features of cytophagic histiocytic panniculitis (see p. 540) was present in one case.⁸²⁶ Conspicuous rhomboidal and needle-shaped crystals were present in the cytoplasm of many lesional plasma cells and histiocytes in one case. Extracellular deposition was also present.⁸⁴⁷

The large histiocytes of Rosai–Dorfman disease are S100⁺ and negative for CD1a (see Fig. 40.25C).^{803,848,849} They also express various macrophage and monocyte markers, such as α_1 -antitrypsin, lysozyme, CD14, CD68, stabilin-1 (a marker of non-Langerhans cell histiocytes),⁵²² and Mac387.^{807,850} Expression of factor XIIIa, a dendrocyte marker, has also been reported,⁸⁵¹ but it has been negative in other cases, as might be expected from its presumed cell of origin.⁸⁴⁵ There are no Birbeck (Langerhans) inclusions in the histiocytes.⁸⁰³

Dermoscopy of a lesion of Rosai–Dorfman disease showed changes similar to those of JXG and solitary reticulohistiocytoma – yellow-orange central area with surrounding erythematous periphery (‘setting sun’), clouds of pale yellow globules, and arborizing telangiectasias – but with a wider range of colors.^{852,853}

Differential diagnosis

Lesions with foamy macrophages and Touton giant cells could be confused with xanthomas or JXG, and those with spindled cells could raise the possibility of dermatofibroma or other spindle cell tumors.¹⁵⁴ However, finding evidence for emperipolesis involving the large macrophages points to a diagnosis of Rosai–Dorfman disease. This is further supported by the cytoplasmic S100 positivity of these cells. In contrast to the S100⁺ cells of Langerhans cell histiocytosis, those of Rosai–Dorfman disease are negative for CD1a and lack Birbeck granules. Other microscopic features more characteristic of Rosai–Dorfman disease include prominent lymphocytic and plasmacellular infiltrates and proliferative thick-walled vessels.

GIANT CELL RICH HISTIOCYTIC DERMATITIS/PANNICULITIS

Although it is most unusual to create an entity, in a textbook, on the basis of a solitary report, the case described with this designation seems sufficiently unique to justify a separate description.⁸⁵⁴ The

Figure 40.25 Rosai–Dorfman disease. (A) There are aggregates of large histiocytes with lightly eosinophilic cytoplasm, admixed with inflammatory cells. (B) A histiocyte contains inflammatory cells within its cytoplasm – an example of emperipolesis. Note that there are also numerous plasma cells. (H&E) (C) The histiocytes are S100⁺. The inflammatory cells within these histiocytes appear as negative images within the granular, S100⁺ cytoplasm. (Immunohistochemistry for S100 protein)

patient, with history of thrombocytosis, presented with a 5-year history of a violaceous, maculopapular rash primarily on her legs. The rash subsequently progressed to form confluent patches and plaques on her torso and arms. The clinical impression was disseminated granuloma annulare.⁸⁵⁴

Histopathology

There was an interstitial dermatitis and a mixed lobular and septal panniculitis with focal lymphoid aggregates.⁸⁵⁴ The interstitial histiocytes had large, irregular nuclei with prominent nucleoli. Scattered, often bizarre multinucleate giant cells were present in the dermis, but they were concentrated near the dermal–subcutis interface. Focal aggregates of mature lymphocytes were present. There were no granulomas or necrobiosis.⁸⁵⁴

The cells expressed CD68 and S100 but not CD1a.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

This rare, life-threatening histiocytosis is characterized by a benign proliferation of histiocytes and an uncontrolled phagocytic syndrome,

described as a ‘cytokine storm’,⁸⁵⁵ induced by T cell activation, which in turn may be due to infections of various types.⁵⁰⁸ EBV is sometimes the triggering infection.⁸⁵⁶ Other examples are scrub typhus⁸⁵⁷ and influenza A (H1N1).⁸⁵⁸ There may be an underlying connective tissue disease, malignancy, or HIV infection that depresses the immune system.⁸⁵⁹

Patients present with fever, splenomegaly, liver dysfunction, cytopenia, hypofibrinogenemia, and tissue hemophagocytosis.⁵⁰² Cutaneous manifestations are present in up to 65% of cases, but they are a minor component of the illness.⁸⁶⁰ There may be hemorrhage from the hypofibrinogenemia. Revised 2004 criteria of the Histiocyte Society are used for diagnosis; these are listed in Table 40.9.⁸⁶¹ Molecular diagnosis involves finding abnormalities in a number of genes involved in immune response pathways.⁸⁵⁵ Helpful in early diagnosis is the finding of a Th1/Th2 cytokine pattern: significant increases in IFN- γ and IL-10 and slightly increased or normal IL-6.⁸⁵⁵

A dysfunction of the cytokine perforin seems to be involved in many cases. Its release may be triggered by the precipitating infection.⁵⁰³ Perforin is implicated in the mechanism of at least two of the four familial hemophagocytic lymphohistiocytosis (HPLH) syndromes. These syndromes have predominantly been reported from areas of

Table 40.9 Diagnostic criteria for hemophagocytic lymphohistiocytosis (HLH)

A diagnosis of HLH can be established if one of either A or B criteria is fulfilled:	
A. A molecular diagnosis consistent with HLH	
B. Diagnostic criteria for HLH (five of the eight following criteria)	
1. Fever	
2. Splenomegaly	
3. Cytopenia (affecting ≥2 of 3 lineages in the peripheral blood)	
Hemoglobin <90 g/l (in infants <4 weeks: hemoglobin <100 g/l)	
Platelets <100 × 10 ⁹ /l	
Neutrophils <1.0 × 10 ⁹ /l	
4. Hypertriglyceridemia and/or hypofibrinogenemia	
Fasting triglycerides ≥3.0 mmol/l (i.e., ≥265 mg/dl)	
Fibrinogen <1.5 g/dl	
5. Hemophagocytosis in bone marrow or spleen or lymph nodes without evidence of malignancy	
6. Low or absent NK cell activity	
7. Ferritin ≥500 µg/l	
8. Soluble CD25 (i.e., IL-2 receptor) ≥2400 U/ml	

Table 40.10 Familial hemophagocytic lymphohistiocytosis syndromes

Type	OMIM	Gene locus	Gene
1	267000	9q21.3–q22	Not characterized
2	603553	10q22	<i>PRF1</i> (encodes perforin)

Europe, including Turkey, and from Japan. They are listed in [Table 40.10](#). Hemophagocytosis can also be seen in cytophagic histiocytic panniculitis. The median survival of untreated cases is 2 or 3 months. Treatment of the triggering infection is the first requirement. Ultimately, hematopoietic stem cell transplantation may be required; it is curative.⁵⁰³

A comprehensive review of the clinical features, diagnosis, and management of this condition has recently been published.⁸⁶²

Histopathology

There is usually nonspecific spongiosis and a mild perivascular infiltrate of lymphocytes and histiocytes.⁵⁰³ There is often focal hemorrhage. The histiocytes in the skin are S100⁺. Some are CD68⁺.

HISTIOCYTIC SARCOMA

Histiocytic sarcoma is the preferred term of the International Lymphoma Study Group for a rare malignant tumor of histiocytes that was formerly called histiocytic medullary reticulosis and later called malignant histiocytosis.⁸⁶³ Many of the earlier cases were not histiocytic when archival material has been subject to current immunohistochemical markers.⁸⁶³ A review of 7 suspected cases seen at the Mayo Clinic during a 20-year period produced only 1 case that had a true histiocytic origin.⁸⁶⁴ Fletcher and colleagues reported 14 cases in 2004.⁸⁶⁵ Clinical features include fever, generalized lymphadenopathy, hepatosplenomegaly, pancytopenia, and sometimes disseminated intravascular coagulation, night sweats, and abdominal pain.^{866–868} The skin is involved in 10–15% of cases, and in some this is the presenting feature.^{869–871} Lesions take the form of papules, nodules, or plaques anywhere on the body but with a predilection for the extremities and

Figure 40.26 Histiocytic sarcoma. The neoplastic cells feature pink, vacuolated cytoplasm and large, irregularly shaped nuclei. (H&E)

buttocks.⁸⁷² Skin involvement mimicked kwashiorkor in 1 case.⁸⁷³ Sometimes only a solitary nodule is present initially. Spontaneous healing of individual lesions may occur. A case of histiocytic sarcoma apparently arose through transdifferentiation of follicular lymphoma; immunohistochemistry supported the former diagnosis, whereas the two tumors had the same immunoglobulin heavy chain and bcl-2 gene rearrangements and t(14;18)(q32;q21) translocation by fluorescence *in situ* hybridization analysis.⁸⁷⁴

Malignant histiocytosis occurs at all ages; some cases have been reported in childhood.^{875–877} Because some of these cases may have been other diseases, it is difficult to be certain of the percentage of childhood cases. The prognosis at all ages is poor, although patients presenting with skin lesions form a subgroup with a more favorable outlook.^{866,869} Prognosis might be related to tumor size.⁸⁶⁵ At autopsy, there is usually involvement of many organs. In the series of 18 cases reported by the International Lymphoma Study Group, the median age of the patients was 46 years; 72% presented with extranodal disease. The mortality rate was 58%.⁸⁶³

Polytherapy consisting of vincristine, cyclophosphamide, doxorubicin, and prednisolone achieved complete remission in 22 of 27 patients in one series.⁵⁰³

Histopathology

Two patterns of cutaneous involvement may be seen.⁸⁷⁰ In one, there is a dense, predominantly periadnexal and perivascular infiltrate of atypical histiocytes; in the other, there is a diffuse infiltrate of similar cells in the deep dermis and subcutis, with focal necrosis. The papillary dermis is usually spared, but if there are cells in this region, there is no associated epidermotropism such as is seen in Langerhans cell histiocytosis.⁸⁷⁸

The cells in the infiltrate show variable pleomorphism, which increases with the passage of time. The cells measure 15–25 µm in diameter and have an oval or reniform nucleus and abundant eosinophilic cytoplasm ([Fig. 40.26](#)). Occasional binucleate cells are present. Phagocytosis of erythrocytes and nuclear debris may be seen, but it is not a universal feature.⁸⁷² There are also some small lymphocytes and plasma cells in the infiltrate.⁸⁷⁸

The nuclear atypia in malignant histiocytosis allows it to be distinguished from the virus-associated hemophagocytic syndrome, histiocytosis X, and cytophagic panniculitis.⁸⁶⁹

In the series of 18 cases reported by the International Lymphoma Study Group and referred to previously, the following phenotype was expressed: CD68 (100%), lysozyme (94%), CD1a (0%), S100 (33%), CD21/35 (0%).⁸⁶³ Concavalin-A is also present.⁸⁶⁷ CD31 may be a marker for some histiocytic malignancies.⁸⁷⁹ A case of histiocytic sarcoma of the peritonsillar region with cutaneous involvement has been reported; it had the immunophenotype of Langerhans cells (CD1a⁺, S100⁺) but lacked Birbeck granules (i.e., indeterminate cells).⁸⁸⁰

Electron microscopy

The histiocytes are noncohesive and sometimes have irregular surface projections.^{866,881} There are many cytoplasmic organelles, including lysosomes and lipid droplets.⁸⁸¹ There are no Birbeck granules. Phagocytosis is sometimes seen in the more differentiated histiocytes.⁸⁸²

REACTIVE HISTIOCYTOSIS

The term 'reactive histiocytosis', also known as secondary histiocytosis, refers to the increased number of histiocytes that may be seen in a variety of cutaneous infections. These include histoplasmosis, toxoplasmosis, brucellosis, tuberculosis, leprosy, rubella, and certain infections with EBV.⁴⁹⁶ Histiocytes are also prominent in actinic reticuloid. Histiocyte-like myeloid cells have been reported in some cases of Sweet's syndrome (histiocytoid Sweet's syndrome).⁸⁸³ In susceptible hosts, particularly those with various immunodeficiency syndromes, infections may trigger idiopathic histiocytic proliferations indistinguishable from Langerhans cell histiocytosis.⁴⁹⁶

A histiocytic infiltrate has also been reported in two patients with acute lymphocytic leukemia receiving cytarabine.⁸⁸⁴ Lesions resolved after cessation of the drug.

INTRAVASCULAR/INTRALYMPHATIC HISTIOCYTOSIS

Intravascular/intralymphatic histiocytosis is a rare, reactive histiocytosis characterized by the proliferation of histiocytes in vascular or lymphatic lumina.⁸⁸⁵⁻⁸⁸⁷ Most of the reported cases have been associated with rheumatoid arthritis,⁸⁸⁸⁻⁸⁹¹ but tonsillitis was the associated condition in another patient.⁸⁸⁷ Intralymphatic histiocytosis in the region of the metal implants has been reported on a number of occasions.⁸⁹²⁻⁸⁹⁴ Granulomas were also present. In a recent report of seven cases by Bakr *et al.*, four were associated with rheumatoid arthritis, one with Crohn's disease, and two had no disease association.⁸⁹⁵ Histiocytes are sometimes seen in dilated lymphatics in the dermis in Rosai-Dorfman disease.⁸⁰⁸

Lesions associated with rheumatoid arthritis are usually asymptomatic, irregularly shaped patches of erythema, sometimes livedo-like, in the vicinity of the involved joint. The case associated with tonsillitis presented with painful induration of the scrotum.⁸⁸⁶

Histopathology

There are heavy intralesional aggregates composed mainly of histiocytes within dilated vessels in the dermis. Thrombosis of vessels was present in the scrotal case (discussed previously).⁸⁸⁷ There is a mild but variable infiltrate of lymphocytes, plasma cells, and sometimes neutrophils in the intervening dermis.⁸⁹⁶ In one report, the intraluminal cells expressed CD68, Mac387, and CD43 but not CD79a, CD20, CD3, or vascular endothelial markers such as CD31 and factor VIII.⁸⁸⁷ The endothelial cells expressed vascular markers but not D2-40, a marker for lymphatic endothelial cells.⁸⁸⁷ However, in three other reports, the intraluminal cells also expressed CD68, but the endothelial cells expressed the lymphatic marker D2-40.^{888,889,892} Furthermore,

in the previously mentioned study by Bakr *et al.*, endothelial cells of involved vessels were D2-40⁺ in all five tested cases.⁸⁹⁵ Tested intralymphatic macrophages also expressed HLA-DR.⁸⁹⁵

XANTHOMATOUS INFILTRATES

Xanthomas represent the accumulation of lipid-rich macrophages known as foam cells.⁸⁹⁷ They present clinically as yellow or yellow-brown papules, nodules, or plaques, with the color depending on the amount of lipid present and its depth below the surface. They are usually associated with disorders of lipoprotein metabolism, although only a minority of individuals with such disorders develop xanthomas.^{897,898}

Xanthomas can be further subdivided on the basis of their clinical morphology, anatomical distribution, and mode of development into the following types: eruptive, tuberous, tendinous, planar, verruciform, and papular.^{897,898} In addition, there are isolated reports in the literature of xanthomas that cannot be fitted into an orderly classification.⁸⁹⁹⁻⁹⁰⁴ One such example is the occurrence of normolipemic xanthomas in association with HIV infection.^{905,906} Another is the solitary xanthoma with prominent epidermotropism simulating balloon cell melanoma.⁹⁰⁷ This latter case may have been a fibrous papule with clear cells and not a xanthoma. It is difficult to explain the occurrence of multiple xanthomas on the ears of a normolipemic adolescent.⁹⁰⁸ Specifically excluded, perhaps arbitrarily so, are the xanthogranulomas (which are not related to disorders of lipoprotein metabolism and which usually possess an admixture of cell types), and the histiocytic, dendrocytic, and Langerhans cell proliferations in which lipid accumulation (xanthomatization) may be a secondary phenomenon.^{898,900,909} Tangier disease and disseminated lipogranulomatosis (Farber's disease), which also possess some xanthoma cells, are not usually included with the xanthomas. The various diseases featuring the presence of xanthoma cells in the skin are summarized in Table 40.11.

Etiology and pathogenesis of xanthomas

Several of the xanthoma types mentioned previously are associated with specific abnormalities of lipoprotein metabolism; more than one type of xanthoma may be present in a particular lipoprotein disorder.^{898,910} The lipids in xanthomas are primarily free and esterified cholesterol, but occasionally other sterols and even triglycerides accumulate. This is usually the result of a high plasma concentration with subsequent permeation of lipoproteins through the walls of dermal capillaries.^{897,911} The lipid is then taken up by dermal macrophages, which evolve into foam cells.^{897,911}

In recent years, attention has been given to the mechanism by which these monocyte-derived macrophages accumulate in the skin. The process is similar to atherosclerosis and involves vascular endothelial cells and adhesion molecule expression.⁹¹² The presence of increased numbers of E-selectin-positive endothelial cells and a decrease in ICAM-1 cells promotes macrophage migration into xanthoma lesions.⁹¹²

There are several possible explanations for the formation of xanthomas in normolipemic states.⁹¹¹ There may be altered lipoprotein content or structure or an underlying lymphoproliferative disease with xanthomatization of cells infiltrating the dermis.⁹¹¹ Finally, local tissue factors may play a role in cases of xanthoma developing in chronic eczema, photosensitive eruptions, erythroderma, and lymphedema; at sites of injury, such as bites, scars, and striae; and in some regressing tumors. The term 'dystrophic xanthoma' has been used for the accumulation of lipid-rich foam cells within an area of abnormal or damaged skin in both normolipemic and hyperlipoproteinemic states.^{913,914} Dystrophic xanthomas may develop in burns scars, lymphedema praecox,⁹¹⁵ laparotomy scars, striae, lichen planus,⁹¹⁶ mycosis

fungoides, and at the sites of mosquito bites, vaccination, herpes zoster, and phlebitis.

The various types of xanthoma are now considered.

ERUPTIVE XANTHOMA

In the eruptive variant of xanthoma, multiple small red-yellow papules with an erythematous halo develop in crops.⁸⁹⁷ There is a predilection for the buttocks and thighs and also the extensor surfaces of the arms and legs.⁸⁹⁸ The lesions become progressively more yellow and eventually resolve spontaneously over several weeks.

Eruptive xanthomas occur in a setting of elevated plasma chylomicrons such as may occur in uncontrolled diabetes mellitus or following the ingestion of alcohol or the use of exogenous estrogens.^{898,917} Rare associations include lipoprotein lipase deficiency,⁸⁹⁸ types IV and V hyperlipoproteinemia,⁹¹⁸ normolipemia,⁹¹⁹ pregnancy,⁹²⁰ the nephrotic syndrome,⁹²¹ chylous effusions,⁹²² hypothyroidism, the use of intravenous miconazole,⁹²³ and the oral ingestion of 13-*cis*-retinoic acid.⁹²⁴ Eruptive xanthomas have followed the use of the antipsychotic drug olanzapine⁹²⁵ and the protease inhibitor ritonavir.⁹²⁶

Figure 40.27 Eruptive xanthoma. Small foam cells are admixed with lymphocytes, macrophages, and neutrophils. (H&E)

The unique case of normolipemic eruptive xanthomas associated with generalized edema is best regarded as a variant of dystrophic xanthomatosis (discussed previously).⁹²⁷

Histopathology⁹²⁸

The architecture of the reticular dermis is disturbed by an infiltrate of cells and extravascular lipid deposits in the form of lace-like eosinophilic material between the collagen bundles. The cellular infiltrate cuffs capillaries and extends throughout the dermis.⁹²⁸ Initially, it is composed of neutrophils and lymphocytes, in addition to histiocytes with a finely stippled cytoplasm.⁹²⁸ Neutrophils may be quite prominent in early lesions, and the absence of foam cells makes the diagnosis difficult on histopathological grounds alone. In established lesions, the lipidization of cells is more obvious, although foam cells are never as obvious as in the other variants of xanthoma (Fig. 40.27).⁹²⁹

Differential diagnosis

In some stages of their evolution, eruptive xanthomas may mimic the changes seen in granuloma annulare, but close inspection for the features mentioned previously allows the distinction to be made.⁹²⁸ Furthermore, doubly refractile lipid can be seen between foam cells in formalin-fixed material in some cases of eruptive xanthoma but not in granuloma annulare.⁹³⁰ In one report, the doubly refractile material was said to resemble urate crystals.⁹³¹

TUBEROUS XANTHOMA

Tuberous xanthomas present a spectrum that ranges from small inflammatory lesions at one end (tuberoeruptive xanthomas) to large nodular lesions at the other. Tuberous xanthomas often form by coalescence of smaller lesions.⁸⁹⁷ They are yellowish in color and are found particularly on the elbows, knees, and buttocks. With treatment of the underlying hyperlipidemia, there is usually slow resolution over many months.

Tuberous xanthomas are most characteristic of familial hyperlipoproteinemia (type III), but they can be seen rarely in homozygous and heterozygous familial hypercholesterolemia,⁹³² which includes autosomal recessive hypercholesterolemia (OMIM 603813) due to mutations in the *ARH* gene at 1p36–p35,⁹³³ hepatic cholestasis,^{934–936} cerebrotendinous xanthoma, and β -sitosterolemia.⁸⁹⁸ This latter condition (OMIM 210250) is autosomal recessive, with the gene localized to 2p21.⁹³⁷ It is caused by mutations in the *ABC68* gene or in the

ABC65 gene, both of which are located at this gene locus.⁹³⁸ Tendinous xanthomas are also present in these latter two conditions, as well as in the hyperlipidemia associated with the protease inhibitor ritonavir.⁹³⁹ Tuberous xanthomas have also been reported in a normolipidemic subject.⁹⁴⁰

Histopathology

There are large aggregates of foam cells throughout the dermis, but there are usually no Touton giant cells or other inflammatory cells (Fig. 40.28). Fibroblasts are increased in number in older lesions, leading to the progressive deposition of collagen.⁹⁴⁰ In one case, concentric layers of xanthoma cells surrounded a cutaneous nerve.⁹⁴¹ In another case, the cells assumed a plexiform pattern – *plexiform xanthoma*.^{942,943}

The lipid within the foam cells can be stained with oil-red O in frozen sections, or it can be examined polariscopically to confirm its doubly refractile property.

TENDINOUS XANTHOMA

In tendinous xanthoma, lesions of varying size develop in ligaments, fasciae, and tendons, especially the extensor tendons of the hands and feet and the Achilles tendon.⁸⁹⁸ They are firm to hard, flesh-colored nodules that develop slowly over decades.

Figure 40.28 Xanthoma tuberosum. (A) Sheets of foam cells involve the dermis. (B) Another case. It is early, and the xanthoma cells are much smaller than in lesions of long standing. (H&E)

Tendinous xanthomas are most commonly associated with heterozygous familial hypercholesterolemia, but they have also been reported in cerebrotendinous xanthomatosis (caused by a mutation in the sterol 27-hydroxylase gene), β -sitosterolemia, familial hyperlipoproteinemia (type III) and hepatic cholestasis, and, rarely, in normolipidemic individuals.^{898,940,944} Cerebrotendinous xanthomatosis (OMIM 213700) is caused by a mutation in the *CYP27A1* gene, which encodes sterol 27-hydroxylase, on chromosome 2q33–qter.

Histopathology

The appearances are similar to those seen in tuberous xanthomas, except for the different tissue substrate (Fig. 40.29).

PLEXIFORM XANTHOMATOUS TUMOR

Plexiform xanthomatous tumor is a normolipemic xanthomatous tumor with a distinctive plexiform pattern, composed of a variable admixture of uniform epithelioid and xanthomatous cells.⁹⁴⁵ Lesions are usually solitary, but up to four lesions may be present. All cases reported have been in males.⁹⁴⁵ Some cases may represent a morphological variant of tuberous or tendinous xanthoma, but lesions are usually smaller than those in these other two variants of xanthoma.

Histopathology⁹⁴⁵

The tumors are located in the dermis and subcutis. As mentioned previously, there is a distinctive plexiform arrangement of epithelioid and xanthomatous cells. Rarely, cholesterol clefts, necrosis, and Touton giant cells are present. There are sparse inflammatory cells. The cells stain with CD68 but are negative for S100, CD34, and cytokeratins.⁹⁴⁵

PLANAR XANTHOMA

Planar xanthomas are yellow, soft macules or slightly elevated plaques that are further subdivided on the basis of their location into xanthelasma, intertriginous xanthomas,⁸⁹⁸ xanthoma striatum palmaris,^{917,946} and diffuse (generalized) plane xanthomas.^{897,898} A further variant, planar xanthoma of cholestasis, is sometimes recognized.^{898,947}

Figure 40.29 Tendinous xanthoma. Foamy macrophages are found within the Achilles tendon. This example occurred in a patient with cerebrotendinous xanthomatosis caused by mutation in the sterol 27-hydroxylase gene. (H&E)

Xanthelasma

Xanthelasma is the best known and most common form of xanthoma and is characterized by one or more yellowish plaques on the eyelids or in periorbital skin.⁹⁴⁸ In one patient, the xanthelasma was unilateral, sparing a paralyzed lid.⁹⁴⁹ Lipid levels are normal in approximately 50% of affected individuals, although in young affected persons there is a higher incidence of hypercholesterolemia.^{897,933,950} Abnormalities in the apoprotein moiety of lipoproteins have been detected in some of those with normal levels of lipid in the blood.^{951–953} Altered vascular permeability may also play a role.⁹⁵⁴ Its association with the hyperimmunoglobulinemia syndrome combined with a lymphoma was probably fortuitous.⁹⁵⁵

Many treatments have been used to remove these unsightly lesions. They include surgical resection, trichloroacetic acid peeling, and treatment with various types of laser, including CO₂ lasers, erbium:YAG laser, or pulsed dye laser.⁹⁵⁶ The 1064-nm Q-switched Nd:YAG laser is another treatment option.⁹⁵⁶

Intertriginous xanthoma

The variant with localization in intertriginous areas is pathognomonic of homozygous (type IIa) familial hypercholesterolemia.^{898,932} Sometimes the xanthomas spread beyond the intertriginous areas.⁹⁵⁷

Xanthoma striatum palmaris

The lesions in xanthoma striatum palmaris, which is characteristic of familial hyperlipoproteinemia (type III), are present on the palms and volar surfaces of the fingers.^{898,946,958} They are sometimes subtle, requiring proper lighting for their recognition.

Diffuse (generalized) plane xanthomas

The rare condition of diffuse (generalized) plane xanthomas is associated with macular, yellowish discoloration of the skin, involving particularly the trunk and neck and sometimes the face.^{954,959,960} Yellow-orange plaques are sometimes present.⁹⁶¹ It usually occurs in adults; childhood cases are rare.⁹⁶² The disease usually runs a protracted course. The majority of patients are normolipidemic, although several hyperlipoproteinemic states have been associated with this variant.⁹⁶³ Increased vascular permeability is sometimes present.⁹⁵⁴ There is a significant association with lymphoreticular neoplasms, particularly myeloma, although these disorders may not become manifest until several years after the onset of the xanthomas.^{964–970} Other associations include adult T-cell lymphoma/leukemia,⁹⁷¹ photosensitivity,⁹⁷² and adenocarcinoma of the rectum.⁹⁷³ Sometimes paraproteinemia, without myeloma, is present.⁹⁶¹ Transformation into necrobiotic xanthogranuloma has been reported.⁷⁶⁰

Histopathology

In xanthelasmas, there are small aggregates of foam cells in the upper dermis. There is no fibrosis, and no other inflammatory cells are present except a mild increase in mast cells (Fig. 40.30).⁹⁷⁴ Plane xanthomas are composed of small groups and streaks of foam cells in the upper dermis and sometimes around pilosebaceous follicles. A few perivascular lymphocytes are sometimes present. Fibroblasts may also be increased in number. Uncommonly, there is a more diffuse infiltrate of foamy macrophages and Touton cells, with cholesterol clefts and necrobiosis resembling the pattern seen in necrobiotic xanthogranuloma.⁹⁶¹

Electron microscopy

Electron microscopy confirms the transition of macrophages into foam cells with lipid inclusions in the cytoplasm.

Figure 40.30 Xanthelasma. Aggregates of foam cells are identified in the dermis, in the absence of fibrosis and with only a few scattered inflammatory cells, some of which are mast cells. (H&E)

VERRUCIFORM XANTHOMA

The verruciform variant of xanthoma is composed of asymptomatic, usually solitary, flat plaques or warty lesions up to 2 cm in diameter.⁹⁷⁵ A giant lesion measuring 15 × 20 cm has been reported.⁹⁷⁶ They may vary in color from gray to pink or yellow, depending on the thickness of the overlying epithelium. There is a marked predilection for the oral cavity,⁹⁷⁷ although lesions have also been reported on the vulva,⁹⁷⁸ perianal skin,⁹⁷⁹ scrotum,^{980–982} penis,⁹⁸³ and occasionally extragenital skin.^{984–986} Multiple papules of the hands and feet have been reported in association with verrucous genital lesions.⁹⁸⁷ Verruciform xanthomas have developed in association with epidermal nevi,^{988,989} a seborrheic keratosis,⁹⁹⁰ a fibroepithelial polyp of the vulva,⁹⁹¹ a squamous cell carcinoma,^{992,993} an arteriovenous hemangioma,⁹⁹⁴ recessive dystrophic epidermolysis bullosa,^{985,995} discoid lupus erythematosus,⁹⁹⁶ and lymphedema of the leg.^{997–1000} They have occurred in immunocompromised patients with HIV-1 infection,¹⁰⁰¹ with graft-versus-host disease,¹⁰⁰² and in association with human papillomavirus (HPV).^{1003–1005} Because similar morphological changes are identified in CHILD syndrome (see p. 292) resulting from mutational inactivation of the 3 β -hydroxysteroid dehydrogenase (NSDHL) gene, located at Xq28, a search was made for mutations in this gene in cases of sporadic verruciform xanthoma. A novel missense mutation in exon 6 of the NSDHL gene was demonstrated in two of the nine patients tested.¹⁰⁰⁶ This mutation is not the usual one encountered in the CHILD syndrome. Lesions may persist for long periods. It is assumed that the formation of the xanthoma cells is secondary to degeneration of or damage to cells in the overlying epithelium.^{984,1001,1007–1009} The xanthoma cells are thought to be derived from dermal dendrocytes.¹⁰¹⁰ Lipid metabolism is usually normal, although verruciform xanthoma has been reported in association with an undefined systemic lipid storage disorder.¹⁰¹¹

Histopathology⁹⁷⁸

On low-power magnification, the lesions often have a verruca-like configuration. There is hyperkeratosis, focal parakeratosis, and verrucous acanthosis (Fig. 40.31). Keratinous columns sometimes extend down into invaginations of the epidermis. There is often prominent exocytosis of neutrophils into the upper layers of the epithelium and the parakeratotic scale.¹⁰¹² The basal layer usually has reduced amounts

Figure 40.31 Verruciform xanthoma. (A) There is marked hyperkeratosis and verrucous acanthosis, with numerous foam cells in the papillary dermis. (B) The foam cells show some nuclear variability. (H&E)

of melanin. Cystic invagination of the surface epidermis has been reported.¹⁰¹³

The papillary dermis is filled with numerous large xanthoma cells. There are variable numbers of lymphocytes, plasma cells, neutrophils, and eosinophils beneath and between the xanthoma cells. The cells contain lipid and small amounts of PAS-positive, diastase-resistant material between the lipid vacuoles. Perivascular hyalinization of superficial vessels is sometimes present. Perifollicular deposits have been reported in patients with clinical features of Fox–Fordyce disease.¹⁰¹⁴

The foam cells are positive for CD68 and weakly positive for cytokeratin and factor XIIIa, but they are negative for S100 protein.⁹⁹¹

Electron microscopy

Electron microscopy has confirmed the presence of lipid vacuoles within the cytoplasm of the foam cells.⁹⁸⁸ One study showed numerous lipid droplets in the cytoplasm of melanocytes in the overlying epidermis. The authors speculated that these cells were the source of the lipid.¹⁰¹⁵

PAPULAR XANTHOMA

Papular xanthoma is a very rare condition consisting of multiple discrete yellow-red papules on the face and trunk and occasionally on

mucous membranes.^{495,524} Only eight cases have been reported, according to a paper published in 2007.¹⁰¹⁶ The condition has been classified with the histiocytic infiltrates because affected individuals are usually normolipidemic;⁴⁹⁵ however, because there are no primitive histiocytes or other inflammatory cells in the lesions, it seems best to classify it as a xanthoma.¹⁰¹⁷ Furthermore, qualitative abnormalities in the lipoproteins may be present.¹⁰¹⁸ Papular xanthoma, particularly in children, may be clinically indistinguishable from JXG.¹⁰¹⁹ Rarely, it is congenital.¹⁰²⁰

Papular xanthomatosis has been reported in a patient with the Sézary syndrome¹⁰²¹ and in one with erythrodermic atopic dermatitis.¹⁰¹⁷

The skin lesions in adults tend to be persistent, although childhood cases are often self-healing within 1–5 years.¹⁰²⁰ An adult case has been treated successfully with doxycycline.¹⁰¹⁶

Histopathology^{524,1022}

There is an infiltrate of foam cells in the upper and mid dermis, with variable numbers of Touton giant cells. There are very few, if any, chronic inflammatory cells within the lesions. Small amounts of hemosiderin are sometimes present within the foam cells and in extracellular locations. The cells are S100[−]. In one reported case, the foam cells stained strongly for factor XIIIa but were negative for Mac387. However, the multinucleate cells expressed this latter marker.¹⁰²³ In another study, the cells were positive for CD68 but negative for S100 protein, CD1a, CD56, and factor XIIIa. The authors concluded that the cells were of macrophage rather than dendrocyte origin.¹⁰²⁴ A similar finding was reported in the large series of 10 cases by Breier and colleagues,¹⁰²⁵ who noted reactivity for macrophage markers such as KiM1p, CD68, and HAM-56.¹⁰²⁵ The opposite conclusion was expressed in a more recent paper, in which the cells expressed CD68 and factor XIIIa but not CD1a and S100, typical of a dendrocyte origin.¹⁰¹⁶

The absence of an inflammatory cell component distinguishes papular xanthoma from xanthoma disseminatum, eruptive xanthoma, and JXG, and clinical features allow its distinction from the other xanthomas.

Electron microscopy

The foam cells are macrophages with numerous lipid vacuoles and some myelin bodies.¹⁰²²

PAPULAR NEUTROPHILIC XANTHOMA

There is one report of three patients with HIV infection who developed a papular facial eruption in association with an IgA gammopathy.⁹⁰⁶ Although there is some clinical similarity with the plane or papular xanthomas associated with lymphoproliferative disorders, the histology of these lesions is unique. A case has subsequently been reported in association with myelodysplastic syndrome.¹⁰²⁶ Patients are normolipemic.

Histopathology

The epidermis is intact with a dermal infiltrate of xanthoma cells. Between the xanthoma cells, there is hyalinized collagen with neutrophils and nuclear dust. Some of the foamy macrophages contain nuclear debris within their cytoplasm.⁹⁰⁶ Microscopically, the lesions have a resemblance to erythema elevatum diutinum, which also occurs in the setting of HIV infection (Fig. 40.32).

LANGERHANS CELL INFILTRATES

The Langerhans cell is one of the dendritic cells, a group of nonphagocytic mononuclear cells that play a role in the trapping and processing

Figure 40.32 Papular neutrophilic xanthoma. (A) Within the dermis are infiltrates of xanthoma cells and aggregates of neutrophils showing leukocytoclasia. (B) High-power view shows the intermingling of xanthoma cells and fragmented neutrophils. Nuclear debris is identified within the cytoplasm of some foamy macrophages. (H&E)

of antigens for presentation to lymphocytes.^{1027,1028} Dendritic cells may be of mesenchymal or hemopoietic stem cell origin.^{502,1029} Other dendritic cells include so-called ‘indeterminate cells’, ‘interdigitating dendritic (reticulum) cells’,¹⁰³⁰ ‘follicular dendritic cells’, and ‘veiled cells’. Tumors of these other dendritic cells are exceedingly rare, with only a few cases reported.^{1031–1035}

Langerhans cells

Epidermal Langerhans cells are derived from bone marrow.⁵⁰³ They account for approximately 2% of the cells in the epidermis.¹⁰²⁷ Like other dendritic cells, they specialize in processing and presenting antigens to T lymphocytes.¹⁰³⁶ Epidermal Langerhans cells are particularly efficient in processing bacterial antigens.^{1037,1038} As Langerhans cells move from the skin and travel to draining lymph nodes, they lose their ability to process antigen and acquire the characteristics necessary to present antigen to T lymphocytes.¹⁰³⁹ In the lymph nodes, the Langerhans cells may be the cells that have been referred to as veiled cells.¹⁰²⁹ Various epidermal cytokines facilitate this functional maturation, including GM-CSF, TNF- α , and IL-1. This mechanism ensures that antigen presenting at the skin surface is translated into an appropriate immune response.¹⁰³⁹ The migratory response of epidermal Langerhans cells to TNF- α decreases in the elderly.¹⁰⁴⁰ They are also reduced in

number with age, and there is atrophic morphology with fewer dendrites and fewer Birbeck granules.¹⁰⁴¹

Langerhans cells are approximately 12–15 μ m in diameter, with clear cytoplasm and an irregularly shaped nucleus. They are situated in the epidermis above the basal layer – a situation that usually distinguishes them from melanocytes in H&E-stained sections and in immunoperoxidase preparations for S100 protein. There is considerable regional variation in the number of Langerhans cells in the epidermis.^{1042,1043} Langerhans cells are also found in the pilosebaceous apparatus, where they localize to the infundibular region of the follicle with extension into the germinative sebaceous epithelium.¹⁰⁴⁴

Ultrastructurally, Langerhans cells possess many organelles, the most characteristic of which is the Birbeck (Langerhans) granule. This is a rod or tennis racquet-shaped organelle of variable length and a constant width of 33 nm.¹⁰²⁷ Similar dendritic cells without Birbeck granules are known as indeterminate cells.¹⁰²⁷ Of interest is the report of a healthy white male whose epidermal Langerhans cells lacked Birbeck granules. The cells appeared to have normal antigen-presenting capacity, suggesting that Birbeck granules are not a prerequisite for normal function.¹⁰⁴⁵

Langerhans cells show esterase, acid phosphatase, and ATPase activity.¹⁰⁴⁶ They express certain antigens, such as CD1a, S100 protein, CD45, CD101, and HLA-DR, and they bind peanut lectin.^{1046–1048} CD1a staining is considered specific for Langerhans cells. Birbeck granules are recognized by the monoclonal antibody anti-Lag (Langerhans-associated granule), but another antigen langerin is also detected with anti-Lag.^{503,1049} Langerin (CD207) acts as an endocytic receptor to translocate ligand from the cell surface into the Birbeck granule. This suggests a functional importance for the Birbeck granule as a novel pathway for antigen processing.¹⁰⁵⁰ Work suggests that the dermis contains dendritic cells that are langerin⁺, which function independently of epidermal Langerhans cells.¹⁰⁵¹ Although epidermal Langerhans cells do not express fascin, a dendritic cell marker in lymphoid tissue and peripheral blood, it is found in the cells of Langerhans cell histiocytosis.¹⁰⁵²

Langerhans cells play an important role in the pathogenesis of allergic contact dermatitis and a lesser role in various other inflammatory dermatoses, such as lichen planus.¹⁰²⁷ They have also been seen in the nodules in scabies, as have indeterminate cells.¹⁰⁵³ Langerhans cells are often increased in number in the epidermis overlying various cutaneous tumors.¹⁰⁵⁴ Flask-shaped pseudo-Pautrier abscesses (Langerhans cell microgranulomas) are sometimes present in spongiotic dermatitides, imparting a pityriasiform appearance.¹⁰⁵⁵ They are sometimes present in allergic contact dermatitis. They possibly result from accelerated migration and activation from peripheral blood and dermal precursors.¹⁰⁵⁵ However, significant infiltrates of Langerhans cells are found only in Langerhans cell histiocytosis (formerly known as histiocytosis X) and congenital self-healing histiocytosis, which is now regarded as a self-limited variant of Langerhans cell histiocytosis.¹⁰⁵⁶ The reduction in Langerhans cell numbers in the vulva in HIV⁺ patients lowers local vulvar immunity and may contribute to the progression of HPV-related vulvar intraepithelial neoplasia.¹⁰⁵⁷ Accumulating evidence indicates that anti-inflammatory drugs target dendritic cells on multiple levels, including maturation, migration, and differentiation.¹⁰⁵⁸

The exact nosological position of the exceedingly rare cases reported as ‘malignant histiocytic neoplasm of Langerhans cell type’ and ‘malignant Langerhans cell tumor’ is uncertain.^{1059–1061} Based on the report of the International Lymphoma Study Group (see later), they would be regarded today as examples of Langerhans cell sarcoma.⁸⁶³ Defining this term is not without its own problems.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis, formerly known as histiocytosis X,¹⁰⁶² is the collective designation for a clinical spectrum of diseases that in the

past were called Letterer–Siwe disease, Hand–Schüller–Christian disease, and eosinophilic granuloma of bone, as well as intermediate and poorly elucidated forms.^{1063–1066} The term *Langerhans cell disease* is now being used.⁵⁰³ It is a rare disease with a prevalence of approximately 0.5/100,000 children per year.¹⁰⁶⁷ However, there are many reports of older adults being affected. The traditional classification into three types has been abandoned because many cases did not conform to these classic subtypes.^{1068–1071} They are mentioned briefly here because they provide a meaningful insight into the clinical diversity of this condition.

Letterer–Siwe disease

Cutaneous lesions are common and extensive in this acute disseminated form of Langerhans cell histiocytosis.¹⁰⁷² They consist of yellow-brown scaly papules on the scalp, face, trunk, and buttocks, which can coalesce to form a weeping erythematous eruption resembling seborrheic dermatitis.⁵²⁴ Sometimes there is a hemorrhagic component, which may resemble the appearance seen in the blueberry muffin baby.¹⁰⁷³ Cutaneous lesions are accompanied by fever, anemia, lymphadenopathy, osteolytic lesions,¹⁰⁷⁴ and often hepatosplenomegaly. Sclerosing cholangitis has been reported.¹⁰⁷⁵ This variant has been reported in monozygotic twins.¹⁰⁷⁶

Hand–Schüller–Christian disease

Hand–Schüller–Christian disease is a chronic multisystem form characterized by the triad of bone lesions, diabetes insipidus, and exophthalmos, although it is uncommon for all three to be seen together in the same patient.⁵²⁴ The skin is involved in one-third or more of cases: the cutaneous manifestations may resemble the lesions of Letterer–Siwe disease or take the form of papulonodular lesions or granulomatous ulceration in intertriginous areas.¹⁰⁷⁷

Eosinophilic granuloma

Cutaneous lesions are quite uncommon in eosinophilic granuloma,^{1078,1079} but when they occur, they take the form of nodulo-ulcerative lesions in the mouth¹⁰⁸⁰ or the perineal, perivulval, or retroauricular regions.^{524,1081}

As mentioned previously, the categorization of Langerhans cell histiocytosis into three clinical groups is now passé, because many cases do not fit neatly into any category.¹⁰⁸² Rare cutaneous presentations have included cutaneous ulcerations^{1083–1085} resembling pyoderma gangrenosum,¹⁰⁸⁶ child abuse,¹⁰⁸⁷ or amebiasis,¹⁰⁸⁸ eruptive xanthoma-like lesions,¹⁰⁸⁹ multiple papules and plaques or nodules,^{1090–1093} prurigo nodules,¹⁰⁹⁴ scattered papular lesions resembling bites,¹⁰⁹⁵ vesicles,^{1096,1097} pustules,¹⁰⁹⁸ lesions resembling cherry angiomas,¹⁰⁹⁹ verruca plana,¹¹⁰⁰ or Darier's disease,¹¹⁰¹ and a solitary lesion on the mons pubis,¹¹⁰² buttock,^{1103,1104} or eyelid.¹¹⁰⁵ Involvement of the nails,¹¹⁰⁶ the genitalia of the elderly,¹¹⁰⁷ and the excision site of a basal cell carcinoma have all been reported.¹¹⁰⁸ Its association with a basal cell carcinoma of the scrotum has also been described.¹¹⁰⁹ Cutaneous lesions are uncommonly the only manifestation of the disease.^{1110–1112} Many of the cases that were reported as 'familial histiocytosis X' appear to have been immunodeficiency syndromes associated with an idiopathic proliferation of histiocytes.^{496,509} Malignant lymphoma and leukemia have been reported in association with Langerhans cell histiocytosis – preceding, following, or concurrent with it.^{1113–1115} Myelodysplastic syndrome and hemophagocytic lymphohistiocytosis have also been reported.^{859,1116} Rarely, patients may present with concurrent Langerhans and non-Langerhans cell histiocytoses.¹¹¹⁷

The prognosis in Langerhans cell histiocytosis depends on the age of the patient, the extent of the disease, and the presence of organ dysfunction.¹¹¹⁸ Children younger than the age of 2 years with multisystem disease and organ dysfunction have a mortality risk of 50% or

more.¹¹¹⁹ A study of 314 cases at the Mayo Clinic found that 77 of these patients had skin and/or mucous membrane involvement, but only 14 of this group had isolated skin involvement, with the other 63 having multisystem disease. Of the 14 cases with isolated disease, 2 had spontaneous remission, and a further 6 were disease free after surgical excision alone.¹¹²⁰ In another study, the prognosis was related to the extent of the disease. If three or more organs/systems were involved, the mortality rate was 26%.¹¹²¹

Langerhans cell sarcoma is the term now used for cytologically malignant cases, which usually have aggressive clinical behavior.^{1122–1124} The International Lymphoma Study Group examined 26 cases of Langerhans cell tumor. The group regarded 17 cases as cytologically typical and 9 cases as cytologically malignant, which it designated as Langerhans cell sarcoma.⁸⁶³ The cases were not easily recognized morphologically, but they were diagnosed on positive CD1a staining.¹¹²² Their death rate was 50% compared to 31% for the 'benign' group. A case in which the cells lacked Birbeck granules has been proposed as an example of indeterminate cell sarcoma.⁷⁹⁵

Spontaneous healing has been reported in several instances,¹¹²⁵ even with multisystem disease,¹¹²⁶ leading to the suggestion that Langerhans cell histiocytosis is a reactive rather than a malignant neoplastic process.^{1127,1128} However, the cell populations are clonal, although this is not synonymous with a malignant phenotype.¹⁰²⁹ In short, it is an enigmatic disease; its pathogenesis does not fit either a truly neoplastic or purely reactive process.¹¹²⁹ An immunohistochemical study of 14 markers showed that the cells in Langerhans cell histiocytosis were 'activated' Langerhans cells,¹¹³⁰ which express various adhesion molecules that are not expressed in normal Langerhans cells.¹¹³¹ Despite these studies, another used the presence of proliferating cell nuclear antigen (PCNA) in many cases as evidence for a neoplastic rather than a reactive process.¹¹³²

The serum S100- β level is elevated in this disease and may prove to be a useful marker to monitor the progress of the disease.¹¹³³

HHV-6 has been detected by PCR techniques in a number of cases. The significance of this observation is currently uncertain.¹¹³⁴ EBV has also been found in cases of Langerhans cell histiocytosis but specifically excluded in other reports.¹¹³⁵

Treatment of cutaneous Langerhans cell histiocytosis is difficult to assess. Most reports deal with single cases. Furthermore, skin-limited disease can be subgrouped into four categories: (1) those that regress spontaneously or are completely excised and do not recur; (2) those that respond to therapy other than excision and do not recur; (3) persistent or recurrent lesions, not responding to treatment; and (4) cases that progress to multisystem disease.¹¹³⁶

Cases involving the skin can be treated with topical carmustine; topical nitrogen mustard; low-dose methotrexate;¹¹³⁷ psoralen plus ultraviolet-A light phototherapy; narrowband ultraviolet-B;¹¹³⁸ oral thalidomide;⁵⁰³ trimethoprim–sulfamethoxazole;¹⁰⁸² topical imiquimod;¹¹³⁹ IFN- α for more widespread skin disease;¹¹³⁶ chemotherapeutic agents, including etoposide;¹⁰⁸² systemic steroids;⁵⁰³ and thalidomide.¹¹⁴⁰ The Japanese Langerhans Cell Histiocytosis Study Group introduced two protocols for the treatment of single-system disease and multisystem disease, respectively. All patients are started on an induction therapy of cytosine arabinoside, vincristine, and prednisolone, followed by maintenance therapy. Poor responders are given an additional cocktail of drugs. Their results have been excellent, with a 5-year survival rate of 100% for single-system disease.¹¹⁴¹

Histopathology

Langerhans cell histiocytosis is characterized by clusters and sheets of large ovoid cells, 15–25 μ m in diameter, with abundant eosinophilic cytoplasm and a nucleus that is indented or reniform and sometimes eccentric – 'coffee bean' nucleus (**Fig. 40.33**).¹¹⁴² The cells are found immediately beneath the epidermis and usually show little tendency

Figure 40.33 Langerhans cell histiocytosis. The cells have a characteristic reniform nucleus. (H&E)

to extend into the reticular dermis, except in nodular lesions.¹¹⁴³ The cells often assume a periappendageal distribution in the papules of adult cases.^{1144,1145} They were noticeably folliculocentric in a case confined to the scalp.¹¹⁴⁶ Focally, the cells invade the epidermis, sometimes forming small aggregates in the upper epidermis (Fig. 40.34). A few lipidized cells may be present in the papillary dermis, but more marked xanthomatous changes are exceedingly rare,¹¹⁴⁷ usually being confined to the Hand-Schüller-Christian variant. Occasional binucleate cells are present, and there are scattered mitoses. A case mimicking melanoma has been reported.¹¹⁴⁸

There is a variable admixture of other inflammatory cells; this will depend on the type of lesion biopsied and, to some extent, the clinical variant of the disease. The cells include neutrophils, eosinophils, lymphocytes, and mast cells.¹¹⁴⁹ In Letterer-Siwe disease, the infiltrate is largely of Langerhans cells, with the admixture of relatively few neutrophils, eosinophils, and lymphocytes, whereas in eosinophilic granuloma, clusters of eosinophils may form a prominent component of the infiltrate (Fig. 40.35). Multinucleate giant cells may be prominent in both eosinophilic granuloma and Hand-Schüller-Christian disease. Other microscopic changes that are sometimes present include focal necrosis and fibrosis in older lesions.¹¹²⁸ Although the outcome cannot be predicted from the histopathological appearances, strong expression

Figure 40.34 Langerhans cell histiocytosis. (A) Langerhans cells and lymphocytes involve the papillary dermis. (B) Another case with epidermal involvement as well. (H&E)

Figure 40.35 (A) Langerhans cell histiocytosis. (B) This is the variant previously known as eosinophilic granuloma, with a mixture of eosinophils and Langerhans cells. (H&E) **(C)** The Langerhans cells stain for S100 protein.

of PCNA by the cells appears to reflect a poor prognosis.¹¹⁴⁴ Apoptosis mediated through the Fas/Fas-L pathway may contribute to the spontaneous regression of lesions in single-system disease.¹¹⁵⁰

Immunohistochemical markers are those discussed previously for the Langerhans cell and include CD1a, HLA-DR, S100 protein, and langerin (CD207).^{1068,1151–1154} The cells also express fascin, which is not a feature of normal epidermal Langerhans cells.¹⁰⁵² There appears to be some immunophenotypic heterogeneity: not all cells stain with a particular marker in an individual case.¹¹⁵⁵ The cells are negative for Mac387, which stains cells of the monocyte–macrophage system but not those of the dendritic cell system.¹¹⁵⁶ The cells do not express CD34 or MS-1, a marker for sinusoidal endothelial cells and dendritic perivascular macrophages, which is found in the non-Langerhans cell histiocytoses.⁵⁰⁷ Note that some cells in B and T cell lymphoproliferative disorders express CD1a.¹¹⁵⁷ They were so numerous in one case of lymphomatoid papulosis that it mimicked Langerhans cell histiocytosis.¹¹⁵⁸ The author has seen several cases in which localized, heavy collections of Langerhans cells were present, presumably as an incidental phenomenon. No further disease has developed in three cases known to the author. One involved the wall of an epidermal cyst. Another involved a vulvectomy specimen for vulvar intraepithelial neoplasia, whereas in the third case, the Langerhans cells were in the base of a leukemic infiltrate of the skin.

Tumor-like eosinophilic granuloma is an extremely rare tumor of the skin composed of eosinophils, neutrophils, and histiocytes that are in part epithelioid and in part foamy.¹¹⁵⁹ Only sporadic cells stain as Langerhans cells. The lesions may resolve spontaneously. The etiology is unknown.

Electron microscopy

The cells are the same in all three clinical variants and more or less resemble normal Langerhans cells. Birbeck granules may be absent in a proportion of cells.¹¹¹⁸ Interestingly, these granules are relatively resistant to destruction by formalin fixation and paraffin embedding, and accordingly they may be seen in material removed from paraffin blocks and reprocessed for electron microscopy.¹⁰⁶⁵

Differential diagnosis

A common diagnostic problem manifests in children with Langerhans cell hyperplasia secondary to other inflammatory processes, including scabies,¹¹⁶⁰ contact dermatitis, and pityriasis lichenoides acuta.¹¹⁶¹ In such cases, a useful approach includes a careful review of the clinical and histopathologic features, additional sectioning to search for scabies mites or their products, or detection of scattered CD30⁺ cells – a feature repeatedly seen in cases of scabies with Langerhans cell hyperplasia.¹¹⁶⁰ Lesions of JXG may bear a resemblance to Langerhans cell histiocytosis, particularly later stage lesions of Langerhans cell histiocytosis in which foamy macrophages and multinucleated cells are often present. The cells of JXG lack the characteristic reniform nuclei of the cells of Langerhans cell histiocytosis and do not show epidermotropism. Numerous, well-formed Touton giant cells are often seen in JXG and are not characteristic of Langerhans cell histiocytosis. Examples of S100⁺ JXG have been reported, but these cells are reliably negative for CD1a, while they also express factor XIIIa and CD68 (the cells of Langerhans cell histiocytosis are also positive for CD68). Xanthoma disseminatum also shares certain clinical and pathologic features with Langerhans cell histiocytosis, but the former condition lacks epidermotropism. In addition, its cells possess scalloped borders and ovoid nuclei, and they express factor XIIIa and CD68 rather than S100 and CD1a. The extensive epidermotropism seen in some cases of Langerhans cell histiocytosis can morphologically resemble that of cutaneous T-cell lymphoma (CTCL). In addition, the expression of CD4 among cells of Langerhans cell histiocytosis could create some diagnostic confusion. However, the cell morphology of Langerhans cell histiocytosis (large cells with eosinophilic cytoplasm and reniform

nuclei) is quite different from that in CTCL; furthermore, other T cell markers are absent in Langerhans cell histiocytosis, whereas S100 and CD1a expression is not seen in the cells of CTCL.

CONGENITAL SELF-HEALING (RETICULO) HISTIOCYTOSIS

Congenital self-healing histiocytosis is a rare infiltrative disorder of the skin described in 1973 by Hashimoto and Pritzker.¹¹⁶² It is now regarded as a self-limited form of Langerhans cell histiocytosis,^{1056,1163–1168} composed of activated mature Langerhans cells.¹¹⁶⁹

The usual clinical presentation is with numerous firm red-violaceous or brown papulonodules, 1–10 mm in diameter, scattered over the scalp, face, and, to a lesser extent, the trunk and extremities.^{1163,1170,1171} Several patients with vesicular or bullous lesions or erosive patches have been reported.^{1172,1173} Only a solitary lesion was present in several reported cases.^{1174–1177} The tumors are usually present at birth, although early postnatal onset has also been recorded.^{1178,1179} It has been reported in monozygotic twins.¹¹⁸⁰ The lesions all regress by 3 months of age, usually leaving residual hyperpigmentation. Relapse and systemic disease are both rare events.^{1181–1183} Long-term follow-up for relapse is essential.¹¹⁸⁴

Histopathology

The histological picture is often indistinguishable from that of Langerhans cell histiocytosis.¹¹⁶³ There is usually a dense infiltrate of large histiocytes in the mid and lower dermis. Extension into the subcutis and papillary dermis may occur; there is usually no significant epidermotropism, although this has been described.^{1179,1185} The histiocytes have abundant eosinophilic cytoplasm with a variable number of PAS-positive granules. Some cells have foamy cytoplasm. The nuclei are oval or reniform. Multinucleate giant cells are invariably present. There are also lymphocytes, mast cells, and some eosinophils in the infiltrate.¹¹⁸⁶ Focal necrosis¹¹⁸⁵ and extravasation of erythrocytes have also been reported.¹¹⁷⁴ Abundant reticulin fibers are often present around groups of cells and sometimes between individual cells.¹¹⁸⁷ It has been suggested that there is a variant with large cells resembling reticulohistiocytoma with intermingled Langerhans cells.¹¹⁸⁸ The nature of this group of cases is uncertain.

The tumor cells usually express CD1a and S100 protein,^{1163,1166} although in one reported case only 30% of the cells were S100⁺.^{1165,1176} In this latter case, none of the cells contained Birbeck granules.¹¹⁶⁵ Cells containing Birbeck granules will express langerin (CD207).¹¹⁶⁹ There is no difference in the expression of E-cadherin, Ki-67, and phosphorylated histone H3 between this condition and Langerhans cell histiocytosis.¹¹⁸⁹ In congenital self-healing histiocytosis, the histiocytes and giant cells are sometimes larger than in Langerhans cell histiocytosis, and some may have foamy cytoplasm.¹¹⁹⁰ These differences are not regarded as sufficient to justify the continued separation of these two conditions.

Electron microscopy

Contrasting with their immunophenotype, only 5–25% of tumor cells contain Birbeck (Langerhans) granules.^{1174,1187,1191} The finding of concentrically laminated dense-core bodies in the same cells that contain Birbeck granules has been proposed as a specific marker for this disease.^{1192,1193} Other cytoplasmic inclusions of unusual shape may also be present, as well as lipid droplets.¹¹⁹²

Primary cutaneous peripheral T-cell lymphoma, unspecified	1191	Other T/NK-cell lymphomas and leukemias	1204	Cutaneous infiltrates in post-transplant lymphoproliferative disorders (PTLDs)	1213
Primary cutaneous aggressive epidermotropic CD8 ⁺ cytotoxic T-cell lymphoma	1192	Other B-cell lymphomas that may involve the skin	1204	Other lymphoproliferative disorders associated with immunosuppression	1214
Cutaneous γ/δ T-cell lymphoma	1192	Precursor B-lymphoblastic leukemia/lymphoma	1204	Methotrexate-associated lymphoproliferative disorders	1214
Primary cutaneous CD4 ⁺ small/medium pleomorphic T-cell lymphoma	1193	Chronic lymphocytic leukemia/small lymphocytic lymphoma (B-CLL)	1205	Cutaneous infiltrates in HIV/AIDS	1214
Cutaneous B-cell lymphomas	1193	Mantle cell lymphoma	1205	Extramedullary hematopoiesis	1214
Marginal zone B-cell lymphoma	1193	Primary effusion lymphoma	1206	Interdigitating dendritic cell sarcoma	1215
Follicle center cell lymphoma	1194	Lymphoplasmacytic lymphoma/Waldenström's macroglobulinemia (LL/M)	1206	Follicular dendritic cell sarcoma	1215
Diffuse large B-cell lymphoma	1196	Burkitt's and Burkitt-like lymphoma	1207		
Diffuse large B-cell lymphoma, leg type	1196				
Diffuse large B-cell lymphoma, other	1198				

INTRODUCTION

The diagnosis and classification of cutaneous lymphomas remain the most challenging areas of dermatopathology. An updated World Health Organization (WHO) classification of tumors of hematopoietic and lymphoid tissues based on the Revised European-American Classification of Lymphoid Neoplasms (REAL) classification of lymphomas was published in 2008.^{1,2} This classification includes some cutaneous lymphomas as subgroups within the main classification framework. At the same time, the Project Group of the European Organization for Research and Treatment of Cancer published a classification of cutaneous lymphomas that came to be known as the EORTC classification of cutaneous lymphomas.³ Those two classifications are based on a combination of histological, clinical, immunohistological, and cytogenetic features. There are certain differences in terminology and emphasis between these two classifications, and the appropriateness of one or other of the classifications has been debated in the literature.⁴⁻¹² The EORTC classification includes only those lymphomas that appeared to be unique to the skin. The REAL/WHO

classification has the advantage of including other lymphomas that involved the skin secondarily or rarely as ‘primary’ cutaneous lymphomas.¹³ Other proposals have been made for a stand-alone classification of cutaneous lymphomas based on the REAL/WHO classification.^{13,14} A consensus classification of cutaneous lymphomas, the WHO/EORTC classification of cutaneous lymphomas, has been published^{15,16} and critiqued in the literature.¹⁶⁻¹⁸ This compromise classification defines ‘primary cutaneous lymphomas’ as lymphomas that present in skin with no evidence of extracutaneous disease at the time of diagnosis. There are some inherent problems with this strict definition of primary cutaneous lymphoma because some putative primary cutaneous lymphomas are associated with systemic spread to other systems at the time of presentation, such as Sézary syndrome and adult T-cell leukemia/lymphoma. The definition does not encompass secondary cutaneous lymphomas. Nevertheless, this classification is widely used, and it is used as the framework for the discussion in this chapter (Table 41.1). Other lymphoma entities that only rarely present in the skin or do so as part of systemic spread of lymphoma from another site are classified according to the general WHO classification of lymphomas.

Table 41.1 The classification of cutaneous lymphomas used in this chapter (based on the WHO–EORTC classification)	
Cutaneous T-cell and NK-cell lymphomas	Primary systemic anaplastic large cell lymphoma
Mycosis fungoides and subtypes Folliculotropic mycosis fungoides Pagetoid reticulosis Granulomatous slack skin	Intravascular T- and NK-cell lymphoma
	Aggressive NK-cell leukemia
	Other T/NK-cell lymphomas and leukemias
	Other B-cell lymphomas that may involve the skin
Sézary syndrome	Precursor B-lymphoblastic leukemia/lymphoma
Primary cutaneous CD30 ⁺ lymphoproliferative disorders Primary cutaneous anaplastic large cell lymphoma Lymphomatoid papulosis	Chronic lymphocytic leukemia/small lymphocytic lymphoma
	Mantle cell lymphoma
	Primary effusion lymphoma
Subcutaneous panniculitis-like T-cell lymphoma	Lymphoplasmacytic lymphoma/Waldenström's macroglobulinemia
Primary cutaneous peripheral T-cell lymphoma, unspecified	Burkitt and Burkitt-like lymphoma
Subtypes of peripheral T-cell lymphoma (provisional) Primary cutaneous aggressive epidermotropic CD8 ⁺ T-cell lymphoma Cutaneous γ/δ T-cell lymphoma Primary cutaneous CD4 ⁺ small/medium pleomorphic T-cell lymphoma Primary cutaneous follicular helper T-cell lymphoma (subtype or follicular helper T-cell overlapping entity)	Plasmacytoma and secondary myeloma
	Other lymphomas
	Hodgkin lymphoma
	Cutaneous infiltrates of leukemias
	Myeloid leukemias, myeloproliferative diseases, and myelodysplastic syndromes
Extranodal NK/T-cell lymphoma, nasal type	Lymphoid hyperplasia mimicking primary lymphoma
Hydroa vacciniforme-like lymphoma (variant)	Lymphoid hyperplasia simulating B-cell lymphoma
Adult T-cell leukemia/lymphoma	Lymphomatoid drug reactions
Cutaneous B-cell lymphomas	Reactions resembling CD30 ⁺ lymphoproliferative disorders
Primary cutaneous marginal zone B-cell lymphoma	Pseudolymphomatous folliculitis
Primary cutaneous follicle center cell lymphoma	Jessner's lymphocytic infiltrate
Primary cutaneous diffuse large B-cell lymphoma, leg type	Acral pseudolymphomatous angiokeratoma
Primary cutaneous diffuse large B-cell lymphoma, other Intravascular large B-cell lymphoma Plasmablastic lymphoma T-cell/histiocyte-rich B-cell lymphoma Lymphomatoid granulomatosis	Cutaneous CD8 ⁺ T-cell infiltrates in HIV/AIDS
	Cutaneous infiltrates in post-transplant lymphoproliferative disorders
	Other lymphoproliferative disorders associated with immunosuppression
	Methotrexate-associated lymphoproliferative disorders
Precursor hematologic neoplasm	Cutaneous infiltrates in HIV/AIDS
Blastic plasmacytoid dendritic cell neoplasm	Miscellaneous
Other T/NK-cell lymphomas that may involve the skin	Extramedullary hematopoiesis
Precursor T-lymphoblastic lymphoma/leukemia	
T-cell prolymphocytic leukemia	
Angioimmunoblastic T-cell lymphoma	

The current diagnosis of lymphomas requires some knowledge of lymphocyte ontogeny and techniques that are used to demonstrate such aspects as cell phenotype, clonality of a proliferation, and cytogenetic features including the presence of viral genetic material. Most laboratories are now able to perform these techniques, including immunohistochemistry, *in situ* hybridization, polymerase chain reaction technology (PCR), and fluorescence *in situ* hybridization (FISH).^{19–22} Flow cytometry is also used for immunophenotyping,²³ but unlike other organs, the number of neoplastic cells present in skin is sometimes small and cells are difficult to extract, particularly those in the epidermis. Enzymatic and mechanical disintegration methods have been used to extract cells.²⁴

Other techniques, such as gene expression profiling using cDNA microarray technology and serum proteomics, are being used to more clearly define subgroups of cutaneous lymphoma, distinguish between cutaneous lymphoma and inflammatory dermatoses, and identify prognostic groups.^{25–30}

The significance of established clonality of either B or T cells in cutaneous lymphoid infiltrates remains a problem of interpretation.^{31,32} Although it has often been stated that lymphocyte clonality is not equivalent to malignancy,³³ demonstration of clonality in the appropriate cellular infiltrate and clinical scenario should be regarded as lymphoma.^{3,34} Follow-up studies on atypical lymphoid infiltrates with demonstrated monoclonal populations of T or B lymphocytes have shown progression to clear-cut lymphoma in some cases.^{34,35} Follow-up may be needed over a long period because of the slow evolution and indolent behavior of many cutaneous lymphomas. Patients with a primary cutaneous lymphoma have an increased risk of developing another lymphoproliferative disorder.³⁶

Most antibodies used for phenotyping and assessment of proliferation are available for use on paraffin-embedded tissue. Currently used antibodies and their various specificities are listed in Table 41.2.³⁷

Techniques such as laser-based microdissection have also helped to identify clonality and extend our understanding of these disorders.^{38–40}

CUTANEOUS T-CELL AND NK-CELL LYMPHOMAS

Cutaneous T-cell lymphomas represent a heterogeneous group of neoplasms that show considerable variation in clinical presentation, histopathology, and prognosis.^{41,42}

The development of techniques to establish T-cell clonality in infiltrates in the skin has greatly contributed to the diagnosis of these disorders; they must still be interpreted in conjunction with conventional histology and immunohistochemistry.^{43,44} Rearrangement of T-cell receptor genes (TCR) $\alpha, \beta, \gamma, \delta$ results in diversity that can be exploited by PCR and Southern blot technology to establish clonality.^{21,45,46} The majority of cutaneous T-cell lymphomas express the $\alpha\beta$ TCR, but all $\alpha\beta$ TCR⁺ cells express at least one rearrangement of the γ -chain allele, and the TCR- γ gene is frequently assayed to establish clonality using a limited number of primers.^{43,44} However, it has been demonstrated that the use of a comprehensive set of primers is required to give an optimal detection rate of TCR- γ gene rearrangements.⁴⁵

It has been suggested that the detection of a clonal process in a polyclonal background is more readily detected with assays directed at the TCR- β locus.⁴⁷ Multiplex PCR assays detect virtually all clonal T-cell populations and have the added advantage of detecting $\gamma\delta$ proliferations.⁴⁸

There are reports of complete regression of cutaneous T-cell lymphomas after biopsy.⁴⁹

KIT (CD117) expression is very rare in all types of primary cutaneous T-cell lymphoma.⁵⁰

Primary cutaneous T-cell lymphomas occurring after organ transplantation are rare and do not have the usual prognosis associated with particular subsets.⁵¹

There are reports of cutaneous T-cell lymphoma evolving from Ofuji papuloerythroderma.⁵² This entity is further discussed on page 592.

MYCOSIS FUNGOIDES AND SUBTYPES

Mycosis fungoides (MF) is a clinically and pathologically distinct form of cutaneous lymphoma characterized by an epidermotropic infiltrate of small to medium-sized T lymphocytes. In the WHO/EORTC classification, the term is reserved for those cases having classic features in which there is progression from patches to plaques to tumors (the Alibert–Bazin type) or variants that have a similar course.^{15,53}

Although it represents almost 50% of all primary cutaneous lymphomas,^{15,54} it is still uncommon. True incidence figures of MF are difficult to collate because clinical subtypes of cutaneous T-cell lymphomas (CTCL) are not clearly distinguished in many registries.^{54–56} There appears to be a rising incidence of CTCL in the United States.⁵⁷ There are differences in incidence among various racial groups.^{57–59} It usually arises in late adulthood.^{60–64} There is a definite male predominance.⁶⁴ It has been reported in identical twins⁶⁵ and very rarely in families^{66,67} or spouses.⁶⁸

Lesions tend to develop on the lower part of the trunk and thighs and also on the breasts in females.⁶⁹ In advanced stages, the entire body may be affected, including the face and scalp. The palms and soles have been involved in some cases. MF typically has an indolent course with slow progression over years or decades.³ In one study of progression of MF from patch stage to death from systemic spread, the overall average disease duration was 12.4 years.⁷⁰

MF is rare in children and young adults.^{64,71–73} Lesions in children are frequently hypopigmented, particularly in dark-skinned individuals.^{74,75} MF arising in children or young adults is not more aggressive than that appearing in adult life.^{72,747} Young patients with limited skin disease may have a slightly better disease-specific survival than older patients.⁷¹

The etiopathogenesis of MF is unknown. There appears to be an association with particular HLA class II subtypes but not HLA class I subtypes.⁷⁶ There is no good evidence that it is linked to viruses such as HTLV-1, HHV-8, or HTLV-5.^{77–89} Most cases of cutaneous T-cell lymphoma in HIV/AIDS patients are erythrodermic, have a CD8⁺ phenotype, and are rapidly progressive. It has been suggested that MF arises in a background of chronic inflammation as a response to chronic antigen stimulation.⁹⁰ There is controversy as to the existence of a preceding stage (premycotic eruption) and its nature.^{91,92} Rare cases have been reported after solid organ transplantation.⁹³

Although the characteristic evolution of MF is from patch through plaque to tumor,⁹⁴ this is not invariably the case.^{71,95}

Intractable pruritus is sometimes present, occasionally preceding the appearance of skin lesions by years.⁹⁶ Histological evidence of MF has been identified in the skin of some of these cases despite the apparent absence of lesions.^{97,98}

Almost all cases of MF are a monoclonal proliferation of CD4⁺ cells. This has been established by PCR for TCR gene rearrangement in 52–90% of cases.³⁴ Not all the cells in lesions are neoplastic: many are reactive.⁹⁹ Micromanipulation and laser-beam microdissection have demonstrated a monoclonal population of T cells in the epidermis in early (patch stage) lesions of MF.^{39,99} Polyclonal (reactive) T lymphocytes are more common in the dermis than are clonal T lymphocytes in these lesions.⁹⁹

Although it is classified as a primary cutaneous lymphoma,¹⁵ circulating clonal T cells can be demonstrated in the peripheral blood even

Table 41.2 Antibodies used in the diagnosis of cutaneous lymphoma and their specificities	
Antibody	Predominant cells
CD1a	Langerhans cells, Langerhans cell histiocytosis, some T-lymphoblastic lymphomas
CD2	T cells and T-cell lymphomas
CD3	T cells and T-cell lymphomas
CD3ε (cytoplasmic CD3)	T cells, NK cells, T-cell neoplasms, NK-cell neoplasms
CD4	T-helper cells, monocytes, macrophages, Langerhans cells, peripheral T-cell lymphomas, MF, HTLV-1 associated adult T-cell leukemia/lymphoma
CD5	T cells, T-cell lymphoma, B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma, mantle cell lymphoma
CD7	T cells, T-cell lymphomas, myeloid leukemia, NK-cell neoplasms, T-cell lymphoblastic lymphoma/leukemia
CD8	T-cytotoxic/suppressor cells, NK cells, T-cell lymphomas (e.g., subcutaneous panniculitis-like T-cell lymphoma)
CD10/(CALLA)	Precursor B cells, B-lymphoblastic leukemia/lymphoma, follicle center cell/follicular lymphoma
CD15	Neutrophils, monocytes, Reed–Sternberg cells (classic Hodgkin lymphoma), acute myeloid leukemia
CD20	B cells, B-cell lymphomas
CD21	Follicular dendritic cells, follicular dendritic cell neoplasms, mantle and marginal zone B cells
CD23	Follicular dendritic cells, mantle zone B cells, B-small lymphocytic lymphoma/chronic lymphocytic leukemia
CD30	Activated lymphoid cells, anaplastic large cell lymphoma, lymphomatoid papulosis, Reed–Sternberg cells (classic Hodgkin lymphoma), embryonal carcinoma
CD43	T cells, myeloid cells, mast cells, T-cell lymphomas, some B-cell lymphomas, myeloid leukemia, mast cell neoplasms
CD45 (leukocyte common antigen, LCA)	Hematolymphoid cells, most B- and T-cell lymphomas
CD45RO	T cells, histiocytes, myeloid cells, T-cell lymphomas, histiocytic neoplasms, myeloid leukemias
CD56	NK cells, subset of activated T cells, T/NK-cell neoplasms, subset of T-cell lymphoma, cutaneous γδ T-cell lymphoma
CD57	NK cells, T-cell subset, subset of T-cell neoplasms, NK-cell neoplasms
CD68	Histiocytes, myeloid cells, mast cells and their neoplasms
CD79a	Immature and mature B cells, B-cell lymphomas, plasma cells, plasma cell neoplasms
CD99	T- and B-lymphoblastic lymphoma/leukemia, small round cell tumors (Ewing's sarcoma/PNET, synovial sarcoma, and others)
CD117 (<i>KIT</i> gene product)	Mast cells and mast cell disorders, some myeloid leukemias, Merkel cell carcinoma
CD123	Plasmacytoid dendritic cells, blastic plasmacytoid dendritic cell neoplasms
CD138	Plasma cells, some B immunoblasts, plasma cell neoplasms, some carcinomas
ALK-1	Some types of anaplastic large cell lymphoma
βF1	Major population of T cells (αβ T cells) not NK cells, most T-cell neoplasms
Bcl-2	Non-germinal center B cells, most T cells, most follicular lymphomas but only some cutaneous follicle center cell lymphomas, many other B-cell neoplasms
Bcl-6	Germinal center B cells, follicular lymphoma including cutaneous follicle center cell lymphoma
BOB.1	B cells including plasma cells, B-cell neoplasms, plasma cell neoplasms
Cyclin D1	Some histiocytes, mantle cell lymphoma
Epithelial membrane antigen (EMA)	Plasma cells, plasma cell neoplasms, anaplastic large cell lymphoma, lymphomatoid papulosis, nodular lymphocyte-predominant Hodgkin lymphoma, many epithelial neoplasms, epithelioid sarcoma
EBV-latent membrane protein-1 (LMP-1)	Hodgkin lymphoma, post-transplant lymphoproliferative disorders, some NK/T-cell neoplasms
Granzyme B, perforin, TIA-1	NK cells, cytotoxic T cells, several T-cell and NK-cell neoplasms
Immunoglobulin light chains (κ and λ)	Plasma cells, plasma cell neoplasms, plasmacytoid neoplasms
Ki-67	Proliferating cells
MUM1	Plasma cells, small percentage of B and T cells, plasma cell neoplasms, lymphoplasmacytic lymphoma, some large B-cell lymphomas, other B-cell lymphomas, Hodgkin lymphoma
Myeloperoxidase	Myeloid cells, myeloid leukemias
Oct-2	B cells including plasma cells, B-cell neoplasms including plasma cell neoplasms
Pax5	B cells except plasma cells, B-cell lymphomas including B-lymphoblastic leukemia/lymphoma, Hodgkin lymphoma, small cell carcinomas and Merkel cell carcinoma
TDT (terminal deoxyribonucleotidyl transferase)	Precursor B, T, or NK cells; B- and T-lymphoblastic leukemia/lymphoma; blastic plasmacytoid dendritic cell neoplasms

in early stages of MF by sensitive PCR techniques.¹⁰⁰ Clones are identical to those in the skin.¹⁰¹

An MF-like picture has been associated with therapeutic ingestion of carbamazepine,¹⁰² captopril,¹⁰³ quinine,¹⁰⁴ fluoxetine,¹⁰⁵ and phenytoin,^{106,107} the eruption cleared in each instance following cessation of the drug.¹⁰⁷

The *patch stage* consists of ill-defined patches of varying hue, often with a fine scale. They are irregular in size and shape and have a random distribution, usually on the trunk. This stage may persist for many years before progression occurs.^{70,108}

It seems appropriate to regard large plaque parapsoriasis (LPP) as early MF because 10–30% of cases progress to overt MF.^{91,109–111} Clonal TCR gene rearrangements have also been identified in a proportion of cases.¹¹² Poikiloderma atrophicum vasculare is the atrophic form of the patch stage of MF.¹¹³ On the other hand, there is less acceptance that small plaque parapsoriasis (digitate dermatosis, chronic superficial scaly dermatitis) is early MF despite views to the contrary (see p. 131).^{96,111,114–116} If progression does occur, it is a rare event. In a study of 27 cases of small plaque parapsoriasis, followed for a mean of 10 years, there was apparent progression to plaque stage MF in only 1 case.¹¹⁷

The *plaque stage* is characterized by well-demarcated lesions that are often annular or arciform in arrangement. They are red to violaceous in appearance and occasionally scaly.¹¹³ The plaques may develop *de novo* or from patches. In the early stages, lesions are often limited to less than 10% of the skin surface, but they may be more widespread, particularly in the late plaque stage.¹¹³

Large plaque parapsoriasis is characterized by irregular erythematous patches with minimal scale rather than plaques as the name implies.¹¹¹ Lesions occur on the trunk and major flexures and are usually larger than 6 cm in diameter.^{109,111} With time, atrophic (poikilodermatous) change may supervene in a proportion of cases.¹¹¹

Tumors usually develop in pre-existing lesions.⁹⁴ The tumors are violaceous to deep red in color, with a tense shiny surface. Ulceration may occur. The lesions usually measure 1 cm in diameter or more.

In one series that examined the progression of the disease through various stages, the average duration of the patch stage was 7.2 years, the plaque stage 2.3 years, and the tumor stage 1.8 years.⁷⁰

The term '*d'emblee form*', used in the past to refer to cases presenting with tumors that were not preceded by patches or plaques, should no longer be used because most represent other T- and B-cell lymphomas that present with tumors.^{42,118}

There is a long list of non-classic presentations of MF^{64,119,120} that although not the typical Alibert–Bazin type have a behavior similar to classic MF. These include hypopigmented lesions,^{121–129} hyperpigmented lesions,^{87,130} leukoderma,¹³¹ bullae,^{132–138} dyshidrotic lesions,¹³⁹ perioral dermatitis-like lesions,¹⁴⁰ palmar–plantar lesions,^{141–143} papules,^{144–147} pustules, acneiform, hyperkeratotic, verrucous,^{148–150} poikilodermatous,¹⁵¹ anetodermic,¹⁵² annular erythema,¹⁵³ granuloma annulare-like,¹⁵⁴ pyoderma gangrenosum-like,¹⁵⁵ and plaques resembling acanthosis nigricans,^{156,157} or keratosis lichenoides chronica.¹⁵⁸

Currently, so-called 'syringotropic MF' is not regarded as a separate entity, unlike folliculotropic MF.^{64,159,160} By itself, it may present with punctate erythema.¹⁶¹ Syringotropism can be seen in otherwise classic MF and in folliculotropic MF (**Fig. 41.1**),^{161–164} and accordingly, lesions may present as typical papules and plaques or multiple comedones and infiltrative plaques with follicular accentuation.¹⁶⁵ In many cases, syringolymphoid hyperplasia, characterized clinically by scaly plaques associated with hair loss and anhidrosis, represents a T-cell lymphoma.^{166,167} Rarely, there may be erythroderma.¹⁶⁸

Acquired epidermal cysts,¹⁶⁹ nail dystrophy,^{169,170} neutrophilic dermatoses,¹⁷¹ and acquired ichthyosis^{172–174} have been reported in association with MF. Second neoplasms including skin cancers, other lymphomas, and internal malignancies have also been reported, some apparently related to therapy.^{175–178} Oral lesions occur rarely.^{179,180}

Figure 41.1 Syringotropic mycosis fungoides. Hypertrophic eccrine glands are surrounded and infiltrated by atypical lymphoid cells. This patient also had folliculotropic mycosis fungoides. (H&E)

MF-associated mucinosis is now classified separately as a variant of MF with folliculotropic MF and is discussed separately.

MF may also present as purpuric lesions (see p. 263) that resemble or are indistinguishable from the pigmented purpuric dermatoses (PPD).^{181–184} Clinical suspicion should be aroused when the distribution of purpuric lesions is unusual for one of the forms of PPD or lesions are extensive, long-standing, and have a reticular pattern.¹⁸¹ The separation of the two conditions is not always possible by routine histology or even with TCR gene rearrangement studies.¹⁸²

Solitary lesions with the histopathology of early MF, and distinct from pagetoid reticulosis, have been reported,^{185–189} sometimes in unusual sites (penis).¹⁹⁰ In one small series of such cases, clonal TCR gene rearrangement was found in 50% of cases. No evidence of progression to classic MF was observed in any of the cases.¹⁸⁶ A recent study of 15 cases and literature review confirmed that solitary MF has a good prognosis.¹⁹¹ It is not clear if these lesions represent true lesions of MF or are simulants.¹⁹² Unilesional folliculotropic MF has also been described, with progression to tumor stage lesions in 2 reported cases.¹⁹³

Erythroderma can develop at any stage in the evolution of MF.⁹⁴ The distinction between Sézary syndrome (SS) and erythrodermic MF is based on the absence of significant numbers of circulating 'Sézary cells' in the peripheral blood as defined later. When hematologic findings fulfill the criteria for Sézary syndrome, the condition is classified as 'secondary SS' or 'SS preceded by MF'.¹⁹⁴ One case of erythrodermic MF was complicated by multi-mononeuropathy due to neural infiltration by mycosis cells.¹⁹⁵

Circulating T lymphocytes exhibiting the same clonal TCR gene rearrangements as those in skin lesions can be found even in early stages of MF.¹⁰¹

Involvement of lymph nodes and other organs may occur in late stages of the disease.¹⁹⁶ Lymphadenopathy in the early stages is due in most cases to dermatopathic lymphadenopathy, a reactive condition that may be seen in lymph nodes draining skin affected by a variety of inflammatory dermatoses as well as MF.¹⁹⁷ However, sensitive PCR techniques have shown involvement of lymph nodes by clonal T lymphocytes even at early stages of MF.^{198–200} Molecular evaluation of lymph nodes for staging purposes has been investigated,^{201,202} but detection of a monoclonal population of T cells by PCR of lymph nodes does not appear to be superior to clinical and histological examination

of lymph nodes in predicting clinical outcomes.²⁰³ Grading of more than one lymph node for staging purposes is reported to be more accurate than for a single node.²⁰⁴ The detection of clonality by Southern blot techniques may be more useful in predicting outcome than using more sensitive PCR techniques.²⁰⁵ One study concluded that detection of a monoclonal population of T cells in lymph nodes by Southern blot analysis¹⁹⁴ or by more sensitive PCR techniques²⁰⁶ was predictive of a poor clinical outcome and reduced probability of survival. Detection of a monoclonal population in peripheral blood is also an adverse feature.²⁰⁷ Visceral involvement is frequently found at autopsy. The lung, spleen, liver, and kidney are most frequently involved, but every organ can be infiltrated by tumor cells.²⁰⁸⁻²¹²

There have been numerous studies on the prognosis and survival in patients with MF.²¹³⁻²²⁰ Different and developing treatment modalities would be expected to alter the prognosis of MF in the future.

The clinical course of MF is quite variable; in the majority of cases, it is indolent. Spontaneous resolution of individual lesions may occur at any time during the disease. The estimated 5-year survival of patients in the EORTC series was 87%.³ Patients are staged T1 to T4 (T1 = limited patch/plaque, T2 = generalized patch/plaques, T3 = tumor, and T4 = erythroderma). Patients with stage T1 disease have a very favorable outcome; their life expectancy is not altered by the disease.²²¹ In a study of long-term outcome for patients with MF and Sézary syndrome, age, stage (T classification), and the presence of extracutaneous disease were important predictors of survival.²¹⁹ Development of extracutaneous lymphoma has been reported in cases of late-stage MF treated with bexarotene.²²² Transformation to a large cell lymphoma²²³ is a poor prognostic feature.²²⁴⁻²²⁷ In one series, those cases with a CD30⁺ large cell transformation had a better prognosis than those with a CD30⁻ phenotype.²²⁶ CD30⁺ large cell transformation has been reported after PUVA and also alefacept therapy for MF.²²⁸ Second B-cell lymphomas have been reported in patients with pre-existing MF.²²⁹ There is also evidence that patients with only patch stage MF can occasionally develop tumors that would qualify for the diagnosis of cutaneous anaplastic large-cell lymphoma, consistent with the observation that MF and another part of the CD30⁺ lymphoproliferative spectrum, lymphomatoid papulosis, can also coexist.²³⁰

Serum thymus and activation-regulated chemokine (TARC/CCL17) levels are useful for assessing the disease activity in patients with MF.²³¹

The outcome of patients with juvenile-onset MF is similar to that of adult-onset disease.⁷³ Pregnancy appears to have no impact on the course of early stage MF.²³² PCR for clonal T-cell rearrangements has identified residual disease in one-third of patients with complete clinical remission.²³³

Histopathology

There is considerable literature on the histological diagnosis of MF, particularly in the early stages.^{234,235} A combination of routine histopathology, immunohistochemistry, and gene rearrangement studies is now possible. All have their limits. Attempts have been made to 'weigh' the importance of various histological parameters in arriving at a diagnosis.^{236,237} Multiple biopsies over a period of time are often needed for a diagnosis. Biopsy appearances can be altered by therapies such as corticosteroids and UVA therapy. Many studies have shown that interobserver agreement on the histological diagnosis of MF is not high.²³⁸ Despite the use of other techniques, some authors maintain that the diagnosis of early MF still depends on clinical features and conventional histology, and they recommend further biopsies where there are no clear-cut diagnostic features in a biopsy.²³⁹

Patch stage

In the patch stage of MF, a combination of architectural and cytological features is used to make the diagnosis. This includes changes in the epidermis and dermis. In the earliest stage, there is a relatively sparse

Figure 41.2 Mycosis fungoides. There is a band-like dermal infiltrate with atypical lymphocytes in the basal epidermis. (H&E)

infiltrate of lymphocytes spread along the slightly expanded papillary dermis with little tendency to aggregate around vessels of the superficial plexus. Within the epidermis, lymphocytes are typically confined to the basal layers of the epidermis, either as single cells in a 'string of beads' arrangement or as small groups of cells (Fig. 41.2). These cells are often surrounded by a clear 'halo', a 'meaningful artifact' not caused by mucin accumulation.²⁴⁰ There is usually little or no spongiosis.^{241,242} The Pautrier microabscess (sharply margined discrete clusters of lymphocytes in close apposition with one another, within the epidermis) is, when strictly defined, highly characteristic of MF (Fig. 41.3). They are uncommon in the patch stage, however, and if this feature is given undue importance, many cases of MF will be missed.^{243,244} Occasionally, the histological appearance mimics a melanocytic lesion. Atypia of cells may be minimal in earlier stages of MF, but in some cases, the epidermal lymphocytes are larger than those in the dermis.⁹² Cytological abnormalities may be seen in thin plastic sections that are not apparent in conventional sections.¹⁰³ There is frequently, but not invariably, fibrosis in the papillary dermis in the form of haphazardly arranged wiry collagen bundles.^{92,103} The epidermis may show mild acanthosis; in poikilodermatous and atrophic lesions, the epidermis is thin.²⁴¹ Necrosis of the epidermis is occasionally present.²³⁴ Basal vacuolar change and pigment incontinence are present in these lesions.²⁴⁵ In some cases, there is a marked lichenoid reaction with histology resembling lichen planus. Unlike lichen planus, there may be plasma cells and eosinophils in the dermal infiltrate as well as atypical lymphocytes. Infiltration of eccrine sweat duct structures may be seen in patch and other stages of MF and may remain after therapy.^{246,247}

The diagnostic changes in large plaque parapsoriasis may be subtle with epidermal changes of mild psoriasiform hyperplasia, overlying mild orthokeratosis and spotty parakeratosis, and a sparse dermal cellular infiltrate. The dermal infiltrate may extend upward into and fill the dermal papillae. Pautrier microabscesses are not seen, and cellular atypia is often minimal.²⁴⁸ The atrophic lesions have identical changes to other atrophic lesions of MF.²⁴⁹

The PPD and pigmented purpuric dermatitis-like lesions of MF may have similar histological appearances. In PPD-like MF, there may be features typical of MF, but some cases have similar features to PPD. Both PPD and PPD-like MF may have lymphocytes aligned in the basal layer of the epidermis and occasional Civatte bodies. Dermal edema is more common in PPD. Atypia of lymphocytes is seen in MF-like PPD, and lymphocytes may be seen in upper levels of the epidermis.¹⁸²

Figure 41.3 Mycosis fungoides. A collection of epidermal atypical lymphocytes forming a Pautrier microabscess. (H&E)

PCR studies may show clonal rearrangements of TCR genes in lichenoid forms of PPD, making distinction of some cases from MF difficult.¹⁸²

Plaque stage

Patch and plaque stages are part of a progression. In plaques of MF, the infiltrate is more dense and atypical lymphocytes are more common. The lymphocytes measure 10–30 μm in diameter, and their nuclei are often obviously indented, ‘prune-like’ or cerebriform. Prominent convolutions are best appreciated in thin sections. Nuclear morphometry of CD3⁺ T cells has been used as a diagnostic technique to distinguish neoplastic T lymphocytes from reactive ones.²⁵⁰ It has been suggested that it is not possible to distinguish MF from spongiotic dermatitis based on identifying lymphocyte atypia alone in routine sections.²⁵¹

Small collections of cells may aggregate around vessels of the superficial plexus and less often the deep plexus. They also extend around adnexae, particularly pilosebaceous follicles.²⁵²

In addition to lymphocytes, the infiltrate usually contains a small number of eosinophils and sometimes plasma cells.²⁴³ Epidermotropism is still a conspicuous feature. Pautrier microabscesses are seen in more than 50% of biopsies; this proportion increases if step sections are examined. Epidermal changes include parakeratosis, mild psoriasiform hyperplasia, and epidermal mucinosis.^{243,253} Mild spongiosis does

not exclude the diagnosis of MF as sometimes claimed,²⁴¹ but spongiotic microvesiculation is rare.²⁵⁴ Spongiotic foci resembling Pautrier microabscesses (pseudo-Pautrier microabscesses) are sometimes seen in spongiotic processes such as allergic contact dermatitis and pityriasis rosea.²⁵⁵ These foci contain monocyte-like cells, Langerhans cells, and rare lymphocytes. Cell nuclei are pale and less complex than in the component cells of true Pautrier microabscesses. These structures are often vase-shaped and appear to open onto the epidermal surface. They may also be seen in MF.^{256,257} Biopsies of apparently normal skin in patients with plaque stage MF sometimes show a mild superficial perivascular infiltrate of lymphocytes, often with epidermotropism.²⁵⁸

Tumor stage

In the tumor stage, the infiltrate has a more monomorphic appearance and is dominated by atypical cells.²⁵⁹ The proportion of tumor cells relative to reactive cells increases. Mitotic figures are easily seen. The entire dermis is often involved, and extension into subcutis may occur. Deep dermal and subcutaneous nodules are particularly likely to occur if electron beam therapy has been given to a pre-existing lesion in the same region.²⁶⁰ Epidermotropism and Pautrier microabscesses are uncommon in the tumor stage. Transformation to a diffuse large cell lymphoma may occur. This was defined in one series by the presence of lymphocytes greater than four times the size of small lymphocytes in more than 25% of the infiltrate or microscopic nodules of the same.²²⁷ The cells can have variable features and resemble the cells seen in anaplastic large cell lymphoma, or they resemble immunoblasts or large pleomorphic cells.

Syringotropism may be the predominant pattern of infiltration with invasion of components of the eccrine coil and duct sometimes associated with proliferation of the epithelial structures.¹⁶¹ Syringotropism can also accompany either epidermal or follicular involvement (or occasionally both); furthermore, in a given patient, one lesional biopsy may show syringotropic changes while another may not.¹⁶⁵ A recent case was accompanied by granulomatous inflammation and reactive B-cell proliferation.²⁶¹

The separation of MF from certain inflammatory dermatoses is not as clear-cut as has been suggested.⁹² There is often disagreement between pathologists in individual cases. Various attempts have been made to provide diagnostic principles, to weigh the importance of particular features, and to standardize reporting of cases.^{262–266} The important histological features in most studies appear to be as follows:

- Pautrier microabscesses
- Lymphocytes with a clear perinuclear halo
- Lymphocytes aligned along the basal layer
- Intraepidermal lymphocytes with hyperconvoluted nuclei
- Epidermal lymphocytes and epidermotropism itself.^{236,244}

Histology is not useful in predicting disease course.²⁶⁷

Granulomas are a rare finding in MF (granulomatous MF).^{254,268–278} They are usually small and tuberculoid in type, but they may be palisaded and mimic granuloma annulare.²⁷⁹ At other times, the granulomas are poorly formed and consist of small collections of multinucleate histiocytes. The granulomas are more localized than in granulomatous slack skin. Granulomas in MF should be distinguished from small collections of lipidized macrophages (dystrophic xanthomatosis), which are rare findings in the dermis in MF.^{269,280,281} A variant with interstitial lymphoid infiltrates superficially resembling granuloma annulare or inflammatory morphea has been reported,^{282,283} as has generalized granuloma annulare associated with granulomatous MF.²⁸⁴ Rarely, there is extensive fibrosis and mucin in the dermis (fibromucinous variant).^{254,285}

Other rare histological changes include the presence of vasculitis²⁸⁶ and the formation of bullae. In the bullous lesions, the split may occur at any level. The majority of cases have been subepidermal in location with negative immunofluorescence.¹³² Signet-ring cells constituted the

infiltrate in one case.²⁸⁷ In hypopigmented lesions of MF, there is a reduction in melanin in the basal cell layer and, sometimes, melanin incontinence.¹²⁴

Epidermal changes such as mild epidermal hyperplasia, dyskeratotic cells, and atypical keratinocytes with large nuclei may be seen following topical treatment with nitrogen mustard.²⁸⁸

Histological mimics of MF have been reviewed.²⁸⁹

Immunohistochemistry and cytogenetics

The tumor cells are typically CD3⁺, CD4⁺, CD45R0⁺, and usually CD8⁻, CD30⁻.²⁹⁰⁻²⁹³ The cells have the characteristics of mature memory cells of the Th2 subset.²⁹⁴ There is variable expression of the T-cell markers CD2, CD5, and CD7.

Tumor cells frequently lack expression of CD7.^{295,296} Although this aberrant feature was thought to be specific for a lymphomatous T-cell process and a useful feature in the differential diagnosis of reactive from neoplastic processes, it has been reported in inflammatory conditions.^{297,298} Loss of several T-cell markers is unusual in reactive processes and would favor lymphoma.^{299,300} Loss of the T-cell marker CD62L has also been used as evidence for a neoplastic T-cell proliferation,³⁰¹ as has a T-cell proliferation that is CD45RB⁺, CD45RO⁻.³⁰² In the tumor stage, there is commonly an aberrant phenotype with loss of T-cell antigens.³⁰³⁻³⁰⁶ Rare cases with similar behavior to classic MF have been reported with a CD4⁻, CD8⁺ phenotype or CD4⁻, CD8⁻.³⁰⁷⁻³¹⁰ Phenotypic shift from CD4⁺ to CD8⁺ has been reported. Cases of hypopigmented MF are particularly likely to have a CD8⁺ phenotype.^{128,129}

Rare CD4⁻, CD8⁺ cases are CD56⁺.³¹¹ Lesions with this phenotype appear to have the same clinical behavior as conventional MF.³¹² Reactive CD8⁺ cells can also be found in the lesions of MF.³¹³ Cytotoxic proteins (TIA-1, granzyme B) are sometimes expressed by the CD4⁺ cells, particularly in late stages of the disease.²⁹⁹ With progression of the disease, some cases may transform to a large cell lymphoma that may be CD30⁺ (secondary large cell anaplastic lymphoma) or CD30⁻.^{224,227,314,315} Such CD30⁺ tumors are not associated with the t(2;5) translocation.³¹⁶ Rarely, CD30⁺ cells are found in appreciable numbers in the patch stage of MF.³¹⁷ MUM1 (multiple myeloma oncogene 1), a marker for plasma cells, late B cells, and activated T cells, is expressed in transformed CD30⁺ cells.³¹⁸ Expression of certain CD44 splice variants may be linked to systemic spread.^{319,320} In addition to lymphocytes, the dermal infiltrate in MF includes numerous dendritic cells that express CD1a or factor XIIIa.³²¹⁻³²³ The T cells within the epidermis usually express proliferating cell nuclear antigen (PCNA). Small B lymphocytes are sometimes present in the dermis in small numbers. Rarely, neoplastic T cells coexpress CD20.³²⁴ Malignant T cells express CCR4 (CC chemokine receptor 4).^{231,278}

In most cases, neoplastic lymphocytes of MF express the $\alpha\beta$ TCR, but rare cases have been reported in which the $\gamma\delta$ receptors are expressed.^{325,326} There are many studies in which the detection of clonal TCR gene rearrangements has been used in the diagnosis of MF, particularly in the early, histologically equivocal lesions of MF.^{34,295,327-332} The significance of demonstrable clonal TCR gene rearrangements in suspect lesions remains controversial to a certain extent, but most authors agree that such a finding warrants clinical monitoring. Many such cases have progressed to frank MF.³⁴ TCR analysis from two different sites has high specificity in distinguishing MF from inflammatory dermatoses.³³³ Unfortunately, early MF is not uncommonly negative for clonal TCR rearrangements.²³⁶

Expression of the Fli-1 transcription factor is associated with progression to tumor stage MF.³³⁴

Complex chromosomal abnormalities have been identified in MF, particularly in the tumor stage, but specific chromosomal translocations have not been identified. Chromosomal loss at 10q and abnormalities in tumor suppressor genes *p15*, *p16*, and *p53* are common.³³⁵⁻³⁴⁰

Figure 41.4 Mycosis fungoides. A mycosis cell with its characteristic indented nucleus. (×12,500)

Electron microscopy

There is a great diversity in the morphology of the atypical lymphocytes in MF. The characteristic cell has a highly convoluted (cerebriform) nucleus with heterochromatin located predominantly beneath the nuclear membrane (Fig. 41.4). The cytoplasm contains multivesicular bodies and mitochondria, which are sometimes clumped. Some authors use the term 'Sézary cell' for a small to medium-sized lymphocyte with a highly convoluted nucleus and the term 'mycosis cell' for a cell that is slightly larger with fewer nuclear indentations.^{341,342} Most authors, however, use the terms 'Sézary cell', 'mycosis cell', and 'Lutzner cell' interchangeably for the various atypical cells, recognizing that intermediate forms also exist.^{108,343}

A much larger cell, sometimes called the 'pleomorphic cell', is seen in the tumor stage. It has a vesicular nucleus and a conspicuous nucleolus.³⁴² The nucleus of the pleomorphic cell may be variably convoluted.

Quantitative electron microscopy has been used to characterize the atypical lymphocytes in MF.^{195,344}

Folliculotropic mycosis fungoides

Folliculotropic MF has been classified as a separate entity to classic MF in the WHO/EORTC classification because it has distinctive clinical and histological features, is more resistant to standard therapies, and has a worse prognosis.^{15,345,346}

The term incorporates pilotropic MF, follicular MF, and MF-associated mucinosis.¹⁵ It has also been reported as follicular cutaneous T-cell lymphoma.³⁴⁷ In this condition, the neoplastic T-cell infiltrate is predominantly folliculocentric, and epidermal involvement can be absent or minimal, although a recent study of 50 cases and a systematic review of the literature found epidermotropism in 54 and 37% of patients, respectively.³⁴⁸ This form occurs predominantly in adults, but there is a broad age range, including children.³⁴⁵ Males are affected more commonly than females. It has been reported in association with lithium therapy.³⁴⁹

The head and neck are the sites most commonly involved.³⁴⁶ Lesions range from grouped folliculocentric papules to plaques and tumors. There is sometimes associated alopecia, cysts, and comedones. It may be associated with nail involvement and ungual mucinosis.³⁵⁰ Rarely, there is erythroderma or Sézary syndrome.^{351,352} Pruritus is common and may be severe.³⁴⁵ As a result of follicular mucinosis, there is mucinorrhea in some cases. An association with other malignant hematologic neoplasms has been reported in 6% of patients with folliculotropic MF.³⁴⁸

The prognosis of this group is generally worse than classic MF,³⁵³ with refractoriness to standard MF therapies.³⁵⁴ There may be transformation to a CD30⁺ large cell lymphoma.^{355,356} Spread to extracutaneous sites has also been reported.^{345,357} Sometimes the progress of the lymphoma is rapid.³⁵⁸ In one large series, the overall survival at 5 and 10 years was 64 and 14%, respectively.³⁴⁵ In another series, the 10-year survival was 82% and the 15-year survival 41%.³⁴⁶

Histopathology³⁴⁵

There is a follicular and perifollicular infiltrate of small to medium-sized lymphocytes with or without FM (Fig. 41.5).^{359,360} The nuclei are often conspicuously cerebriform. The infiltrate may also be present around vessels and the eccrine apparatus, sometimes extending into

eccrine epithelium in a similar manner to that in the follicle. Mucin may be minimal or form small pools in the follicular epithelium. This can be highlighted by Alcian blue stains. Pautrier microabscesses are occasionally present.³⁶¹ Involvement of the epidermis is not present or is minimal.

Follicular dilatation and follicular cyst formation may be evident (Fig. 41.6). A granulomatous reaction to ruptured follicular epithelium is seen occasionally.^{362–364}

Sometimes there is marked basaloid follicular epithelial hyperplasia, ‘basaloid folliculolymphoid hyperplasia’,³⁶⁵ or trichilemmal follicular hyperplasia.³⁶⁶ A similar proliferation of eccrine epithelium is sometimes seen, and there is overlap with so-called ‘syringolymphoid hyperplasia’, many cases of which represent a T-cell lymphoma. Inflammatory cells including eosinophils and plasma cells are commonly seen in the infiltrates.³⁶⁷ Small numbers of B cells are also present; rarely, they may be in such number as to mimic a B-cell neoplasm.³⁶⁸ Sometimes there is an interstitial dermatitis-like pattern.³⁶⁴

In more advanced cases, there may be more confluent infiltration of the dermis, and larger atypical cells are more common.

Immunohistochemistry and cytogenetics

The atypical lymphocytes have CD3⁺, CD4⁺, CD8[−] phenotype. Scattered large atypical CD30⁺ or CD30[−] cells are commonly seen, and

Figure 41.5 Mycosis fungoides-associated follicular mucinosis. (H&E)

Figure 41.6 Pilotropic (follicular) mycosis fungoides. (A) Dilated follicle with atypical lymphoid infiltrate. (B) There is a follicular infiltrate of cerebriform T cells. (H&E)

they may become more confluent in large cell transformation. It has been suggested that the involvement of hair follicles is related to the overexpression of intercellular adhesion molecule-1 (ICAM-1) by keratinocytes in the hair follicle.³⁶⁹

Differential diagnosis

As implied previously, the most important differential diagnostic problem in MF is its distinction in early stages from benign, reactive inflammatory processes, particularly forms of spongiotic dermatitis, a prime example being allergic contact dermatitis. These inflammatory conditions can show rather dense dermal infiltrates and exocytosis of lymphocytes, including collections of cells within the epidermis that can mimic Pautrier microabscesses, although they are usually present within the context of spongiosis – a feature that is often (but not invariably) absent in MF. In addition, the Pautrier microabscess simulators in spongiotic dermatitis often assume a vase-like shape.²⁵⁷ Activated T cells with small but irregularly shaped nuclei can be seen in chronic inflammatory processes (including contact dermatitis), whereas degrees of cytologic atypia in early MF are frequently minimal.²⁴¹ Despite these problems, it is generally recognized that traditional light microscopic diagnosis is the gold standard for the early diagnosis of MF.²⁴³ Therefore, numerous studies have been undertaken to establish morphologic criteria for diagnosis. Reviews of large numbers of cases of MF have emphasized the diagnostic importance of lymphocytes, singly and in small clusters, within the epidermis (in the absence of spongiotic vesiculation). Other important findings include the previously mentioned haloed cells; lymphocytes singly distributed along a broad front of basilar epidermis; a dermal infiltrate that includes plasma cells and eosinophils as well as lymphocytes; and papillary dermal fibrosis, with singly dispersed lymphocytes permeating wiry collagen.^{241,243} The significance of these features has been supported in a statistical analysis of the histopathologic features of MF, along with the presence of hyperconvoluted intraepidermal lymphocytes and epidermal lymphocytes that are larger than dermal lymphocytes.²⁴⁴ When found, Pautrier microabscesses are diagnostically useful, but they are present only in a minority of cases.²⁴⁴ Despite widespread knowledge of these microscopic features, there has continued to be a lack of diagnostic agreement among pathologists.²³⁸ In an attempt to standardize pathology reporting of MF, Guitart and coworkers developed a microscopic grading system. Their major criteria are based on density of the dermal infiltrate, prominence of epidermotropism, and degree of cytologic atypia; minor criteria are related to papillary dermal fibrosis, atypia of intraepidermal lymphocytes relative to those in the dermis, and lack of inflammatory features. In this system, a score of 7 or greater is considered diagnostic for MF.²⁶⁶ Computer-assisted morphometric analysis has been used to enhance the evaluation of nuclear irregularities in cutaneous infiltrates. Such an analysis can improve the ability to discriminate early MF from histologic mimics such as contact dermatitis.³⁷⁰ Immunohistochemistry can also be of value. An infiltrate composed of 70% or greater T cells (as assessed by pan-T-cell markers), with a CD4-to-CD8 ratio of 6 or greater, permits a high level of discrimination between CTCL and other disorders. Although there are problems regarding the specificity of CD7 deficiency, as noted previously, this finding can gain significance when combined with other immunohistochemical features or gene rearrangement studies. For example, discordant expression of CD7 within the epidermis (loss of expression) and dermis (retained expression) can be helpful in distinguishing MF from inflammatory dermatoses in selected cases (the same is true for CD5 and TCR- β expression).³⁷¹ With regard to molecular testing, recent work suggests that combined TCR- β and TCR- γ testing can be of help when faced with this situation because they can maximize negative predictive value when clinical suspicion of MF is moderately high and maximize positive predictive value when pretest probability of having MF is moderately low.³⁷²

Actinic reticuloid, a chronic photodermatitis associated with erythema, induration, and demonstrable sensitivity to a variety of wavelengths of light, can closely resemble MF, with lesions demonstrating both exocytosis and formation of Pautrier-like microabscesses. However, there is a predominance of CD8⁺ cells in the epidermis in actinic reticuloid – a finding that differs from most cases of MF. The demonstration of photosensitivity or T-cell receptor gene rearrangements tends to support the diagnoses of actinic reticuloid or MF, respectively. However, two patients with photosensitivity and lack of T-cell receptor gene rearrangements did progress to microscopic and genotypic MF.³⁷³ A study is needed that provides a detailed comparison of the lymphocyte antigen profiles of these two conditions. An MF-like dermatosis also occurs in association with a variety of drugs, including phenytoin and carbamazepine. This can present as a Sézary-like erythroderma or as plaque-type lesions.^{102,374} Microscopically, the findings can be quite similar to those of MF, and numerous lymphocytes with cerebriform nuclei are observed. The immunohistochemical profile shows a marked CD4 predominance.¹⁰² Keys to the diagnosis may include an absence of T-cell receptor gene rearrangements³⁷⁵ and often rapid resolution of the dermatosis on discontinuation of the offending drug.^{102,374,375} However, both oligoclonality and monoclonality have been reported in drug-induced lymphoid hypersensitivity.^{47,376}

Pagetoid reticulosis

Pagetoid reticulosis (Woringer-Kolopp disease)^{377,378} is a rare distinct variant of MF that presents clinically as large, usually solitary, slow-growing, erythematous, scaly or verrucous patches or plaques.^{379–381} Lesions are typically found on the distal part of the limbs. It has been described on the penis.³⁸² Adult males are predominantly affected. Cases in childhood are extremely rare.³⁸³ A recent case of adult T-cell leukemia/lymphoma presented as pagetoid reticulosis involving the palms and soles.³⁸⁴

A prolonged disease-free survival after simple excision or local irradiation is usual. Extracutaneous dissemination has not been reported.³

Ketron–Goodman disease, which has widely disseminated lesions and a different clinical course, is now regarded as a separate disorder – either a variant of MF or primary cutaneous aggressive epidermotropic CD8⁺ T-cell lymphoma (see p. 1192).^{15,385,386}

Histopathology

The epidermis is characteristically infiltrated by large atypical mononuclear cells with pale eosinophilic cytoplasm, a large nucleus, and prominent nucleolus (**Fig. 41.7**).^{387,388} Cells are arranged singly or in nests or clusters. This produces a pattern resembling Paget's disease or melanoma. Atypical cells are present at all levels of the epidermis but are most prominent in the lower third.³⁷⁹ Cells in the upper layers of the epidermis may show subtle degenerative changes.³⁸⁷ There are scattered mitotic figures. The epidermis is markedly acanthotic with overlying hyperkeratosis and patchy parakeratosis.

Unlike MF, there are no atypical cells in the dermis, which contains a dense, banal infiltrate of small lymphocytes, histiocytes, and some plasma cells.³⁸⁷ There are usually no eosinophils.

Immunohistochemistry and cytogenetics

Tumor lymphocytes have a CD3⁺, CD4⁺, CD8[−] or CD3⁺, CD4[−], CD8⁺ immunophenotype. CD30 is sometimes expressed.^{380,389–391} CD7 and CD62L expression may be reduced, with preservation of other pan-T-cell markers.³⁸⁰ The neoplastic T cells express the adhesion molecules cutaneous lymphocyte antigen (CLA; recognized by the monoclonal antibody HECA-452) and $\alpha_E\beta_7$.^{392,393} These molecules interact with E-selectin and E-cadherin on epithelial cells, and their expression may partly explain the pagetoid growth pattern and unique biologic behavior of these tumors.³⁹³ Clonal rearrangements of TCR genes have been

Figure 41.7 Pagetoid reticulosis. There is marked epidermotropism of atypical lymphocytes. (H&E)

demonstrated. This is usually an $\alpha\beta$ TCR gene rearrangement but rarely may be an $\gamma\delta$ rearrangement.^{390,394,395} Neoplastic cells have been reported to express cutaneous lymphocytic antigen (HECA 452), a skin homing receptor, which might explain the exquisite epidermotropism of this lesion.³⁹⁰

Electron microscopy

Although it is not made clear in most studies, there appear to be two cell populations in the epidermis – cells having features of histiocytes and stimulated T lymphocytes.^{396,397} The latter are the major component; they display cerebriform nuclei, resembling those of MF.^{379,398}

Differential diagnosis

The major differential diagnostic consideration in pagetoid reticulosis is MF, particularly unilesional MF. Although it may not always be possible to distinguish the two, pagetoid reticulosis is most often characterized by verrucoid plaques localized to distal extremities, with microscopic changes that include neoplastic cells confined to the epidermis; a dermal infiltrate restricted to reactive cells with sparse or absent eosinophils; and neoplastic T cells that are more likely to be

Figure 41.8 Granulomatous slack skin. There is a deep dermal lymphoid infiltrate. The most striking findings are the large multinucleated histiocytes containing numerous nuclei. (H&E)

CD8⁺ or CD4⁺/CD8⁺, to express CD30, and to demonstrate a high proliferation rate as demonstrated by Ki-67 positivity.

Granulomatous slack skin

Granulomatous slack skin is a very rare cutaneous lymphoma in which pendulous folds of skin develop in large pre-existing erythematous plaques.^{399–402} There is predilection for flexural areas, particularly the axilla and groin.⁴⁰³ There is a clonal infiltrate of CD4⁺ T cells in the dermis associated with granulomatous inflammation. This condition occurs predominantly in males.³ Most patients have an indolent course, although in one-third of patients there is an association with Hodgkin's lymphoma.^{269,399,404,405} It may also be associated with classic or folliculotropic MF.^{402,406} Another complication reported in 2007, large cell transformation, resulted in the death of the affected child.⁴⁰⁷ Recurrence of the pendulous skin folds after surgical excision has been reported.³⁹⁹ Rarely, there is evidence of extracutaneous lymph node involvement.⁴⁰⁸

Histopathology³⁹⁹

Early lesions exhibit a superficial, or superficial and deep, perivascular lymphocytoid infiltrate; psoriasiform epidermal hyperplasia; slight spongiosis; parakeratosis; and occasional lymphocytes in the lower half of the epidermis. Occasional multinucleate histiocytes are seen in the dermal infiltrate. In established lesions, there is permeation of the entire dermis and the subcutis by a dense infiltrate of small lymphocytes with convoluted nuclei. Characteristically, there are many multinucleate giant cells scattered uniformly throughout the lymphocytic infiltrate. These giant cells contain large numbers of nuclei (Fig. 41.8). Their cytoplasm may contain lymphocytes and elastic fibers. Cellular infiltrates in the upper dermis may be band-like. The dermis between the cellular aggregates is markedly edematous or fibrotic.

Stains for elastic tissue show a complete absence of elastic fibers from the dermis. Occasionally, calcified elastic fibers are seen.^{400,409} The epidermis is infiltrated by lymphocytes, either singly or in small clusters in a pattern similar to the patch or plaque stage of MF.

Immunohistochemistry and cytogenetics

The small lymphoid cells are CD3⁺, CD4⁺ T cells. The multinucleate cells express histiocyte markers such as CD68.^{410,411} Rarely, large CD30⁺

cells are part of the infiltrate.⁴¹² The neoplastic cells are generally $\alpha\beta$ T lymphocytes, and clonal TCR rearrangements of the β chain have been demonstrated.^{401,409,413} Occasional cases demonstrate a clonal γ -chain rearrangement⁴⁰⁸ or do not demonstrate a clonal rearrangement.⁴¹⁴ A translocation t(3;9)(q12;24) has been demonstrated in one case.⁴¹⁵

SÉZARY SYNDROME

Sézary syndrome (SS) is an uncommon form of cutaneous T-cell lymphoma. In the United States, the incidence is approximately 0.3 per 10⁶ persons.⁵⁷ In the current WHO/EORTC classification, it is designated as an entity distinct from MF, although some would regard it as a manifestation of MF⁴¹⁶ or a leukemic stage of MF.⁴¹⁷

A study of the phenotype of T cells from SS and MF patients has shown differences between the two: T cells from the blood of SS patients expressed the lymph node homing molecules CCR7 and L-selectin and the differentiation marker CD27 (features consistent with central memory T cells), whereas T cells from skin lesions of MF lacked these markers but did express CCR4 and CLA (characteristics of skin resident effector memory T cells).⁴¹⁸

The International Society for Cutaneous Lymphomas (ISCL) recognizes several variants of erythrodermic cutaneous T-cell lymphoma, with erythroderma being defined as diffuse erythema involving 80% of the skin surface. Within this spectrum is SS, which may arise *de novo* or following MF; erythrodermic MF, which lacks the hematologic findings of SS; and erythrodermic cutaneous T-cell lymphoma, not otherwise specified.¹⁹⁴

Sézary syndrome was defined historically by the triad of erythroderma, lymphadenopathy, and circulating atypical mononuclear cells in the peripheral blood.⁴¹⁹ Lymphadenopathy, although common in SS, is no longer considered requisite for the diagnosis.

The circulating atypical T cells with hyperconvoluted 'cerebriform' nuclei (a nuclear contour index of 6.5 or more) have been called 'Sézary' or 'Lutzner' cells: there are small and large variants.⁴¹⁶ They can be recognized in blood films stained by the Giemsa or Wright methods, but cell counts using smears may underestimate numbers.⁴²⁰ These cells are not specific for SS and may be seen in small numbers in other cutaneous inflammatory conditions and in normal blood.¹⁹⁴

The ISCL defines SS as generalized erythroderma with hematologic criteria that include an absolute Sézary cell count of at least 1000 cells/mm³; a CD4:CD8 ratio of 10 or more; aberrant expression of pan-T-cell markers CD2, CD3, CD4, and CD5; and increased lymphocyte counts with evidence of T-cell clonality in the blood and a chromosomally abnormal T-cell clone.¹⁹⁴

Russell-Jones developed an algorithm for the diagnostic separation of erythrodermic T-cell lymphoma and non-neoplastic causes of erythroderma.⁴²¹

Less constant clinical features include cutaneous edema, alopecia, nail dystrophy, and palmar and plantar keratoderma.⁴²² Rarely, bullous lesions,⁴²³ plane xanthomas,⁴²⁴ vitiligo,⁴²⁵ leukoderma,⁴²⁶ or a monoclonal gammopathy⁴²⁷ may develop. Peripheral blood eosinophilia is present in many cases.^{55,428} Increased blood immunoglobulin levels are also common.⁴²⁹

Prognostic parameters are still being investigated, but visceral involvement, advanced age, long interval before diagnosis, previous history of MF, circulating Sézary cell counts of more than 5% of the total lymphocyte count, and the presence of the Epstein-Barr virus (EBV) genome in keratinocytes are unfavorable prognostic features.^{417,430,431} In one series, the 5-year survival rate was 33.5%.⁴³⁰ Death is frequently due to systemic opportunistic infections as a result of immunosuppression.⁴³²

Sézary syndrome usually develops in late adult life. Cases in childhood are extremely rare.⁴³³ It may be preceded by another chronic

inflammatory dermatosis such as atopic dermatitis.⁴³⁴ One study found no causal relationship between atopy and SS or MF, however.⁴³⁵ It has been reported in association with infliximab therapy⁴³⁶ and following exposure to ionizing radiation.⁴³⁷ Development of typical lesions of MF has been reported after remission of primary SS,⁴³⁸ and secondary SS may follow folliculotropic MF.⁴³⁹ Large cell transformation in skin, lymph nodes, and peripheral blood has also been reported.^{440,441} There is an increased risk of squamous cell carcinoma of the skin, Hodgkin's lymphoma, and internal malignancies in patients with SS.^{177,442,443}

Some cases of erythroderma have demonstrable T-cell clones in blood without fulfilling the criteria for SS or erythrodermic MF.⁴⁴⁴

Histopathology^{424,445-447}

There is great variability in the histological findings. In many cases, they are similar to those in MF.^{3,448} The same problems of specificity apply as with the early stages of MF discussed previously. In up to 40% of cases, however, the biopsy appearances are nondiagnostic.^{449,450} Multiple biopsies may be more successful in obtaining a histological diagnosis of SS. Topical and other therapies often mask or obliterate diagnostic changes. Nonspecific histological findings are common in SS even when a circulating T-cell clone is present in blood.⁴⁵¹ In one author's experience, the diagnosis of SS could be established with greater certainty by hematologic studies rather than by skin biopsies.⁴⁵⁰

In the most frequently observed histological patterns in SS, there is a perivascular or less often a band-like cellular infiltrate involving the papillary dermis and sometimes the upper reticular dermis as well.⁴⁴⁶ Epidermotropism is present in some of these cases, and Pautrier abscesses may be found, particularly if multiple sections are examined (Fig. 41.9).⁴⁴⁶ In one recent series, epidermotropism was minimal or absent in 61% of cases.⁴⁴⁷ The infiltrate is of varying density and is composed of small lymphocytes admixed with some larger cells with indented or cerebriform nuclei. Lymphocytic cellular atypia may be minimal or inapparent.⁴⁴⁷ Atypical lymphocytes can be seen in spongiotic processes,⁵⁶ and some fixation protocols can produce apparent nuclear atypia.⁴⁴⁷ The use of ultrathin sections enhances the detection of these cells. The cellular infiltrate is present in a background of variable epidermal changes, which include irregular acanthosis of the epidermis with orthokeratosis and focal parakeratosis. Spongiosis is sometimes present although usually mild.⁴⁴⁵ The papillary dermis is fibrotic with thickened collagen bundles and scattered melanophages.

Figure 41.9 Sézary syndrome. There is psoriasiform acanthosis. A rare Pautrier microabscess is identified, and there is a tendency of atypical lymphocytes to 'line up' along the dermal-epidermal junction. (H&E)

Eosinophils and plasma cells may be found in small numbers. Prominent ectasia of papillary dermal vessels is present in many cases and is more pronounced than in patch/plaque lesions of MF.⁴⁵²

Rarely, noncaseating granulomas may be seen in the dermal infiltrate, sometimes after therapy.⁴⁵³

Immunohistochemistry and cytogenetics

The neoplastic lymphocytes in the skin and blood are CD3⁺, CD4⁺, CD45RO⁺, CD8[−], CD30[−], and frequently CD2[−], CD7[−]. Studies employing double staining for CD4:CD8 ratios greater than 10 in skin biopsies have been deemed unhelpful in making a diagnosis.⁴⁵⁴ Circulating clonal CD4⁺ T cells have been shown to express the skin and lymph node-homing chemokine receptors CCR4, CCR10, and CCR7. Both SS and MF are positive for programmed death 1 (PD-1), a cell surface protein that negatively regulates immune responses.⁴⁵⁵ Increased expression of Twist protein (a transcription factor that may promote solid tumor progression by protecting cancer cells from apoptosis) appears to be associated with advanced stages of MF and SS.⁴⁵⁶ Clonal TCR gene rearrangements are present in most cases and are critical if histology and immunohistochemistry are unhelpful. Analysis for TCR gene rearrangements by either PCR⁴⁵⁰ or Southern blot techniques may be difficult to perform in skin biopsies because of the small number of cells in the infiltrate and problems in extracting cells from skin. Demonstration of clonality in circulating T cells in the peripheral blood aids in the differentiation of SS from other non-neoplastic forms of erythroderma.⁴⁵⁷ The presence of the same T-cell clone in skin and blood is strong evidence of SS in the absence of diagnostic histological changes.^{458,459} Flow cytometric counts of CD4⁺/CD7[−] cells in peripheral blood have shown a significant correlation with the number of circulating Sézary cells.⁴⁶⁰ In some cases, however, the cells are CD4⁺/CD7⁺, which obscures the phenotypic distinction between neoplastic and normal T cells.^{430,461} Diminished expression of CD3 and lack of CD26 expression have been used to detect and enumerate atypical cells in the blood in SS.^{461–463}

A case of Sézary syndrome-like erythrodermic cutaneous T-cell lymphoma with a CD8⁺, CD56⁺-type phenotype has been described.⁴⁶⁴

Both SS and MF can express markers of follicular helper T cells, specifically CD10, bcl-6, PD-1, and CXCL-13. This finding could lead to confusion with other cutaneous T-cell lymphomas that display this particular phenotype, including angioimmunoblastic T-cell lymphoma, peripheral T-cell lymphoma with a follicular growth pattern, peripheral T-cell lymphoma not otherwise specified, CD4⁺ small/medium-sized pleomorphic T-cell lymphoma, and anaplastic large cell lymphoma.⁴⁶⁵

Cytogenetic studies show that complex karyotypes are common in SS.^{335,466} Amplification of the *JUNB* gene involved in helper T-cell function has been identified.⁴⁶⁷

Using quantitative reverse-transcriptase PCR methods, T cells from SS patients express significant mRNA levels of T-plastin (PLS3), Twist, CD158k/KIR3DL2 (a member of a family of killer cell immunoglobulin-like receptors), and NK cell p46-related protein (NKp46) – a combination of findings that can yield a highly accurate diagnosis of this syndrome.⁴⁶⁸

Electron microscopy

Sézary cells have a convoluted nucleus with deep and narrow indentations. The cytoplasm has a number of fibrils. Ultrastructural morphometry has been used to distinguish Sézary cells in the blood from normal and reactive lymphocytes, although this technique is rarely used in routine practice.⁴⁶⁹

Differential diagnosis

Cutaneous changes may be nonspecific, resembling those of erythroderma due to other causes. At the same time, benign forms of erythroderma can occasionally display microscopic features suggesting

Sézary syndrome, one example being pseudolymphoma due to phenytoin therapy.³⁷⁴ Circulating cells with morphologic characteristics of Sézary cells can be observed in patients with contact or atopic dermatitis or exfoliative psoriasis.⁴⁷⁰ Therefore, close clinical follow-up, repeat biopsies, and evaluations of blood and lymph nodes are important.^{446,451} T-cell receptor gene analysis or other newer molecular methods as mentioned previously⁴⁶⁹ can be decisive. In cases of pseudolymphoma due to phenytoin therapy, discontinuation of the drug is associated with sustained remission of signs and symptoms.³⁷⁴

ADULT T-CELL LEUKEMIA/LYMPHOMA

Adult T-cell leukemia/lymphoma (ATLL) is a T-cell lymphoma resulting from infection with human T-cell lymphotropic virus type 1 (HTLV-1), a type C retrovirus.^{471–473}

The virus is endemic in southwestern Japan and the Caribbean as well as certain areas of South America and Africa. It has also been reported sporadically in areas of Europe and the southeastern United States.^{474–478} HTLV-1 is transmitted by sexual contact, breast-feeding, infected blood products, and percutaneously.^{474,477} Familial clustering has been described.⁴⁷⁹ The average age of onset of ATLL in a large series from Japan was 57 years (range, 24–92 years).⁴⁷⁹ It is very rare in children. Immigrant studies suggest there is a long latent period from viral infection to overt ATLL.⁴⁸⁰

Several clinical forms are recognized; they have been divided into four groups by Shimoyama:⁴⁷⁹

1. An aggressive acute form seen in approximately 65% of patients and associated with a very high white cell count, hepatosplenomegaly, hypercalcemia, and lytic bone lesions
2. A chronic form associated with lower white cell counts and no hypercalcemia. Lymphadenopathy and hepatosplenomegaly may be present as well as skin manifestations
3. A smoldering form with normal lymphocyte counts in blood but with 1–5% ATLL cells. Skin and lung infiltrates may be present
4. A lymphomatous form with no lymphocytosis, less than 1% circulating ATLL cells, and isolated lymphadenopathy or extranodal tumors.

A purely cutaneous form that resembles MF has also been described.^{479,481} It presented with erythematopapular and tumoral lesions and could be regarded as a fifth, albeit distinctly uncommon, form of ATLL.⁴⁸² The integration pattern of HTLV-1 proviral DNA may be the explanation for the heterogeneity in the behavior of ATLL.^{483,484}

Skin manifestations are often the initial manifestation of ATLL (50–70% of cases); they are found in all forms of the disease.^{485,486} Lesions are often widespread and have many forms, including erythematous patches, plaques, papules, and tumors. Erythroderma and vesiculobullous and purpuric eruptions are less common cutaneous manifestations.^{487–489} Presentation as an isolated single skin nodule is very uncommon.⁴⁹⁰ Nonspecific skin lesions or prurigo may precede the onset of acute ATLL.^{491,492}

The prognosis depends on the clinical subtype; it is worse in the acute and lymphomatous variants, with survival of 2 weeks to 1 year.¹⁵

Atypical lymphocytes are found in the blood in 50–80% of patients at presentation; virtually all develop a leukemic phase eventually.⁴⁹³

A study by Sawada *et al.* indicates that the type of skin eruption is an independent prognostic variable in ATLL; patch and plaque lesions are associated with better survival rates, whereas erythrodermic, nodulotumoral, and multipapular lesions have a poor prognosis.⁴⁹⁴

Histopathology

The cutaneous lesions of ATLL share some features with MF in having an infiltrate of atypical lymphocytes in the upper dermis with variable epidermotropism and occasional Pautrier microabscesses. Unlike MF,

Figure 41.10 Adult T-cell leukemia/lymphoma. There is extensive epidermotropism with Pautrier microabscess formation. Characteristic apoptotic debris is just visible. (H&E) (Case kindly supplied by Dr Tetsunori Kimura, Section of Dermatology, Sapporo General Hospital, Sapporo, Japan)

these microabscesses may contain prominent apoptotic fragments (**Fig. 41.10**). In the nodule and tumor stage, the dermal infiltrate is more extensive, confluent, and atypical and can extend into the subcutis. As in the tumor stage of MF, epidermotropism is less apparent.⁴⁸⁷ In some cases, the infiltrate conforms to a papular outline, an uncommon pattern in MF.¹⁰³

The infiltrating cells may be medium to large size, sometimes with pleomorphic or polylobated nuclei.^{474,485} Other elements, such as small lymphocytes, histiocytes, eosinophils, and plasma cells, are less common than in MF. Sometimes dermal aggregates form, resembling granulomas.^{495,496}

Atypical lymphocytes are sometimes seen in the lumina of blood vessels in the dermis. Angiocentric and angiodestructive lesions are rare manifestations of ATLL.⁴⁸⁶

Immunohistochemistry and cytogenetics

The neoplastic cells are T lymphocytes exhibiting clonal TCR rearrangements. They are usually CD2⁺, CD3⁺, and CD4⁺. Rarely, the cells express a CD4⁺, CD8⁺⁴⁹⁷ or CD4⁺, CD8⁻ phenotype.⁴⁸⁹ They are CD5⁺ and CD7⁻. The cells also express CD25, which is a distinguishing feature between ATLL and Sézary syndrome.^{498,499} The CD4⁺/CD25⁺ phenotype is one shared with regulatory T cells, as is the expression of CCR4.⁵⁰⁰ There is also expression of PD-1 and PD-ligand 1 (PD-L1), reflecting, in part, the immunosuppressed state associated with this disease.⁵⁰⁰ Large lymphoblastoid cells are CD30⁺ and ALK⁻.^{501,502} HTLV-1 is clonally integrated in T cells in all cases and can be demonstrated in paraffin-embedded tissue.⁵⁰³

No distinctive karyotype or molecular abnormality has been identified in ATLL. Cytogenetic studies have shown a complex karyotype.^{478,504}

Electron microscopy⁴⁸⁵

The tumor cells show slight to marked nuclear irregularity with a convoluted shape and a speckled chromatin pattern. The circulating lymphocytes have been termed 'flower cells'.⁴⁷⁸ The degree of nuclear indentation is much less than in the cells of MF and SS. The cells in ATLL have lysosomal granules and glycogen in their cytoplasm.

Differential diagnosis

ATLL must be distinguished from MF and SS (referred to here, for purposes of discussion, as other forms of CTCL). As with these forms

of CTCL, ATLL can present with cutaneous plaques, nodules, or erythroderma. However, ATLL is more likely to present with extensive systemic disease, including lymph node and marrow involvement and hepatosplenomegaly.⁵⁰⁵ Although the microscopic configuration of these lymphomas can be quite similar in skin, a higher proportion of neoplastic to non-neoplastic cells is seen in perivascular zones in ATLL, and those cells are more likely to possess deeply basophilic cytoplasm (especially demonstrable with Giemsa stain). Giant cells with irregularly contoured nuclei are a characteristic of ATLL but not CTCL.⁵⁰⁶ Skin lesions of ATLL have higher levels of interleukin (IL)-2 receptor α genomic RNA than CTCL lesions.⁵⁰⁷ A definitive diagnosis of ATLL rests on the identification of HTLV-1 proviral DNA in tissues. Angiocentric lesions of ATLL can resemble two other angiocentric lymphomas – lymphomatoid granulomatosis and extranodal NK/T-cell lymphoma, nasal type. In lymphomatoid granulomatosis, the perivascular T cells are morphologically bland, and the atypical lymphocytes mark as B cells. B-cell rather than T-cell clonality is demonstrable, and there is an association with EBV rather than HTLV-1. Unlike ATLL, extranodal NK/T-cell lymphoma, nasal type tends to involve sinonasal tissues, is composed of NK cells that are CD56⁺ and possess cytotoxic granule proteins (including granzyme B), and is also associated with EBV.⁵⁰⁸

PRIMARY CUTANEOUS CD30⁺ LYMPHOPROLIFERATIVE DISORDERS

The primary cutaneous CD30⁺ lymphoproliferative disorders are linked by the common histological feature of large atypical lymphoid cells expressing CD30.³ CD30 is a 120-kDa transmembrane cytokine receptor to the tumor necrosis factor receptor family and is preferentially expressed by activated lymphoid cells.

As well as the conditions discussed here, CD30 labels large proliferating T- and B-cell blasts in reactive lymphoid tissue,^{225,509} Reed-Sternberg cells and variants in classic Hodgkin's lymphoma, proliferating cells of other B- and T-cell lymphomas, and other non-lymphoid neoplasms such as embryonal carcinoma.⁵⁰⁹

The primary cutaneous CD30⁺ lymphoproliferative disorders include primary cutaneous anaplastic large cell lymphoma (C-ALCL), lymphomatoid papulosis (LyP), and cases that do not fit clearly into these categories – borderline cases. Distinction between C-ALCL and LyP is not always possible on the basis of histological criteria, and classification is based on clinical presentation and course as well as the histological appearance of lesions. Borderline cases are those that do not fit either classification; clinical follow-up may allow assignment to the appropriate group.⁵¹⁰ The Notch signaling pathway may play a role in the pathogenesis of this group of disorders.⁵¹¹

Primary systemic anaplastic large cell lymphoma involves both lymph nodes and extranodal sites. The skin is commonly involved (21% of cases). Although skin lesions have identical morphology to those in C-ALCL, this form involves a different age group and has a different prognosis. Up to 85% of these tumors express anaplastic large cell lymphoma kinase protein (ALK). In most cases, this results from the translocation t(2;5), in which part of the nucleophosmin (NPM) gene on chromosome 5 is juxtaposed to part of the ALK locus on chromosome 2, resulting in expression of the chimeric oncogenic tyrosine kinase NPM-ALK. The ALK-1 antibody is directed to the cytoplasmic portion of the ALK protein.⁵¹² In 15–20% of cases expressing ALK, there is a variant translocation and not the t(2;5) translocation.⁵¹³ It is discussed further later.

Primary cutaneous anaplastic large cell lymphoma

This form of lymphoma represented 9% of primary cutaneous lymphomas in the EORTC series.³ This lymphoma occurs predominantly

in older adults (median age, 60 years) and is rare in children and adolescents.^{514,515} There is a male preponderance.⁵¹⁶ Most patients have solitary or localized papules, nodules, and tumors that are red to violaceous in color and often ulcerated. Some single lesions resemble keratoacanthoma.⁵¹⁷ Single lesions may arise in uncommon sites such as the penis.⁵¹⁸ Partial or complete spontaneous regression occurs in up to 25% of cases.⁵¹⁹ This may be related to interactions of CD30 and its ligand (CD30L) and death receptor-mediated apoptosis.^{520,521} Cases previously reported as regressing atypical histiocytosis represent this form of ALCL.^{522,523} A transient lesion has been reported associated with cyclosporine (ciclosporin) therapy.⁵²⁴ Cases of C-ALCL demonstrate abnormal expression of the activator protein-1 (AP-1) transcription factor JUN.⁵²⁵

The prognosis is very good, but occasionally there are cases that disseminate in the skin and spread to involve lymph nodes and other sites, and these have a poorer prognosis.^{526–528} In one series, disease-specific survival for localized versus generalized disease was 91 and 50%, respectively.⁵²⁷ Patients with multifocal disease are more likely to develop extracutaneous disease.^{526,529}

C-ALCL has been reported in association with atopic eczema,⁵³⁰ psoriasis,^{531,532} internal malignancies,^{533,534} and B-cell lymphomas.^{535,536} It may also arise after solid organ transplantation.^{160,167,537–541} In very rare cases, CD30⁺ circulating cells can be detected in the blood.⁵⁴²

C-ALCL can arise in patients with previous LyP. In this situation, it is difficult to distinguish it from histological type C LyP. It behaves like conventional C-ALCL in this situation and has a good prognosis.⁵⁴³ It has been reported in patients with concurrent patch stage MF⁵⁴⁴ and in patients who develop LyP after C-ALCL.⁵⁴⁵ LyP, MF, and C-ALCL appear to be clonally related in such patients.^{546,547}

Histopathology

There is an infiltrate in the dermis and sometimes the subcutis that typically consists of confluent sheets of large, CD30⁺ cells (Fig. 41.11). The majority of these cells are typical anaplastic cells with round, oval, or indented nuclei ('hallmark' or 'buttock' cells), prominent nucleoli, and copious cytoplasm. In some cases, the cells are more pleomorphic or immunoblastic in appearance. Some cells resemble Reed–Sternberg cells. A small cell variant with intermediate-sized atypical cells has also been described.⁵⁴⁸ Rare lesions have a sarcomatoid appearance, with spindle cells in a storiform arrangement within a myxoid stroma.⁵⁴⁹ Cell type does not appear to affect prognosis.⁵²⁶ There may be a significant component of small lymphocytes, eosinophils, neutrophils, and histiocytes that in some cases may obscure the neoplastic cells.⁵⁵⁰ There is evidence that neutrophil-rich examples of C-ALCL (sometimes called the 'pyogenic variant') have a worse prognosis than other types of C-ALCL with lymph node involvement; this may be related to the increased proportion of neutrophil-rich cases that express EMA and CD8 – a phenotype more similar to systemic ALCL.⁵⁵¹ This is most prominent in the lymphohistiocytic and neutrophil-rich variants.⁵⁵² The epidermis is generally not infiltrated by tumor cells – although this has been reported⁵⁵³ – but there is often ulceration; folliculotropism has been rarely described.⁵⁵⁴ Rare cases have a 'signet-ring'-like morphology.⁵⁵⁰ In some cases, there is considerable epidermal hyperplasia.⁵¹⁷ Epidermotropism, tumor necrosis, vascular invasion and destruction, and nerve involvement are also present in some cases.⁵⁵⁰ Angioinvasion and angiodestruction may be prominent features in rare cases; thus far, cases with these features appear to have a prognosis similar to that of most other examples of C-ALCL.^{555,556} The infiltrating cells are CD30⁺. In the cases of Kempf *et al.*, they also expressed a cytotoxic, CD8⁺ phenotype; spontaneous regression of lesions suggested a relationship to the recently described angioinvasive, type E variant of lymphomatoid papulosis (see later).⁵⁵⁵ Xanthomatous change may be seen after radiation therapy.⁵⁵⁷

Figure 41.11 (A) Primary cutaneous anaplastic large cell lymphoma. (H&E) (B) Many cells exhibit a positive Golgi zone. (Immunoperoxidase stain for CD30)

Immunohistochemistry and cytogenetics

More than 75% of the neoplastic cells are CD30⁺.⁵¹⁶ The majority are CD3⁺, CD4⁺, CD8[−]. A small number of cases are CD8⁺.^{15,558–560} Most, but not all, are EMA[−] and ALK[−].^{225,561} The presence of a positive reaction for ALK generally indicates cutaneous spread of primary systemic ALCL rather than C-ALCL.⁵⁶² Rare cases showing a positive cytoplasmic reaction for ALK without the usual t(2;5) translocation or variant translocations have been reported.⁵⁶³ A rare example of C-ALCL with both nuclear and cytoplasmic ALK positivity has been reported; the case recurred and eventually progressed to systemic involvement.⁵⁶⁴ Positive reactions for CD15 in a cytoplasmic and Golgi zone pattern have been reported in a small number of cases.⁵⁴³ Cells may express cytotoxic markers TIA-1 and granzyme B as well as CD56.^{565–567} Neoplastic cells may express the cutaneous lymphocyte antigen HECA 452, which is not usually expressed in primary systemic ALCL.⁵⁶⁸

They also express MUM1.³¹⁷ The *IRF4* gene encodes MUM1, also known as interferon regulatory factor-4, a transcription factor expressed in activated T cells, some B cells, plasma cells, and their related neoplasms. FISH analysis demonstrated a translocation at the *IRF4* locus in 20% of tested C-ALCL cases and 3% of lymphomatoid papulosis cases but none of the other tested cases of T-cell lymphomas (including systemic-ALCL). This resulted in a specificity and positive predictive

value of this translocation for C-ALCL of 98 and 90%, respectively.⁵⁶⁹ In the vast majority of cases, the cells do not express EBV by PCR or *in situ* hybridization.^{521,561,570}

MicroRNA (miRNA) profiling using quantitative real-time PCR shows differential expression of certain miRNAs (155, 27b, 93, 29b, and 92a) between C-ALCL and tumor stage MF.⁵⁷¹

The majority of cases are of T-cell type and exhibit clonal β or γ TCR gene rearrangements.⁵⁷² Atypical cells lack the t(2;5) translocation except in rare cases.^{573,574}

Clusterin expression, a marker for systemic anaplastic large cell lymphomas, can also be expressed by C-ALCL.^{575,576} Cells also express the cytokines CCR3 and CCR4^{528,577} and the cell surface adhesion molecule CD44.^{578,579} CD95 (APO-1/Fas) is strongly expressed in C-ALCL and LyP, and it may play a role in regression of lesions.⁵⁸⁰

Differential diagnosis

The CD30 antigen is in reality an 'activation' marker, shared by ALCL, lymphomatoid papulosis, other non-Hodgkin's lymphomas, and non-lymphocyte-predominant Hodgkin's lymphoma.⁵⁸¹ Some benign reactive lymphoproliferative conditions, such as those seen in EBV infections and other immunoblastic viral reactions, may likewise express CD30; therefore, this determinant should never be used as a 'stand-alone' indicator of malignancy. The latter point is important in considering whether ALCL and selected forms of Hodgkin's disease (e.g., the 'syncytial' nodular sclerosing variant – extraordinarily rare in the skin) are related. CD15, CD30, CD45, CD117, EBV-related markers, and fascin are not reliable discriminants among these neoplasms,^{582,583} and they can also be seen in lesions presenting as lymphomatoid papulosis.⁵⁸⁴ Therefore, tissue should routinely be submitted for cytogenetic analysis and ALK-1 immunostaining if ALCL is a potential diagnostic consideration. As noted previously, clusterin, a cell-aggregating protein encoded by a gene on chromosome 8p21, is present in ALCL; however, it is not found in Hodgkin's disease.⁵⁸⁴ The rare sarcomatoid form of C-ALCL could certainly be confused with true sarcomas. Potential morphologic clues to the diagnosis include scattered cells with features of mononucleated Reed–Sternberg cells and, in one recent report, the finding of epidermotropic foci. Immunohistochemical staining can then lead to the correct diagnosis, as can the finding of more typical changes of C-ALCL in other lesions.⁵⁴⁹

Lymphomatoid papulosis

Lymphomatoid papulosis (LyP) is a chronic lymphoproliferative disorder characterized by the appearance of crops of papules, nodules, and sometimes large plaques at different stages of development. Lesions spontaneously regress after several weeks or months, sometimes resulting in atrophic scars. The clinical course may extend over decades. Initially, the lesions are smooth, but later they become necrotic, crusted, and ulcerated.^{585–591} There may be only a few lesions or many hundreds present during each exacerbation.³⁵⁷ They occur mainly on the trunk and proximal parts of the limbs, but they may also arise on the face, scalp, palms, and soles. Lesions rarely involve mucosal surfaces.⁵⁹² There is a predilection for females in the third and fourth decades of life. LyP also occurs in children.^{593–595} Rare clinical presentations include pustular lesions,⁵⁹⁶ localized (agminated) lesions,^{597,598} lesions with a white halo,⁵⁹⁹ and a pattern resembling hydroa vacciniforme.⁶⁰⁰ It has been associated with the hypereosinophilic syndrome,^{601–603} atopic dermatitis treated with cyclosporine,⁶⁰⁴ and parathyroid nodular hyperplasia.⁶⁰⁵ Lesions in pregnant women may regress after delivery.⁶⁰⁶ Keratoacanthoma has also been reported in association with LyP.^{607,608}

There is an increased frequency of prior, coexisting, or subsequent lymphoproliferative disorders associated with LyP: this is most com-

monly MF or Hodgkin's lymphoma.^{609–614} It has been claimed that in approximately 5–10% of cases, there is progression to a malignant lymphoma (Hodgkin's lymphoma, MF, or ALCL) or myeloproliferative disorder.^{358,394,609,615–627} Subsequent neoplasms may demonstrate identical clonal TCR gene rearrangements to those in LyP.^{614,628}

In a study of LyP associated with MF, LyP preceded MF in 67% of cases, followed MF in 19% of cases, and occurred concurrently in 14% of cases.⁶²⁹

Clonal T cells similar to those in skin lesions have been rarely identified in bone marrow and blood.^{630,631}

LyP has an excellent prognosis. In a study of 70 patients by the EORTC group, no patient died of malignant lymphoma and the 5-year survival was 100%. Similar survival figures were reported in another series.⁵²⁷ There is evidence that positive T-cell receptor gene rearrangements or mixed-type LyP may indicate a greater likelihood of progression to lymphoma.⁶³²

LyP is not associated with EBV⁶³³ or human herpesvirus type 6 (HHV-6) and HHV-7, but a study reported an association of LyP with HHV-8.^{561,634–636}

The histological appearance of LyP suggests that it is a lymphomatous process, and most would now regard this condition as a low-grade cutaneous T-cell lymphoma, part of a spectrum with C-ALCL.⁶³⁷ Some still classify LyP as a 'pseudolymphoma'.⁶³⁸ Several studies have identified a clonal population of T cells in 60% of the lesions in LyP,^{588,639–641} but a clonal population is not always identified.⁵⁴⁷ In one study, a clonal population was found in only 22% of archival cases of LyP by PCR.⁵⁷² Single cell analysis of CD30⁺ cells in one study found a single T-cell clone in all cases including anatomically and temporally separated lesions; CD30⁺ background cells were polyclonal.⁶⁴²

Because the histopathological and immunophenotypic features of LyP overlap with C-ALCL, the clinical appearance and course are important features in separating the two conditions and choosing treatment options.³ Lesions of C-ALCL tend to be few and localized, whereas LyP presents as recurring crops of multiple, widely dispersed lesions that involute spontaneously. Some cases have overlapping features and are classified as 'borderline'. Spontaneous regression can occur in both LyP and C-ALCL. Borderline cases with follow-up may ultimately be classified as LyP or C-ALCL but overall have a favorable prognosis.⁶⁴³ It has been suggested that in LyP, cell-mediated immune reactions involving the small lymphocytes may play a role in the spontaneous regression of lesions.⁶⁴⁴

Histopathology⁶⁴⁵

The appearance of the lesions varies to a certain extent according to their age. There are currently five overlapping histopathological subtypes of LyP: types A, B, C, D,^{646–648} and E.^{649–651}

LyP type A is characterized by a wedge-shaped, mixed cellular dermal infiltrate that includes a variable number of large atypical cells similar to those in C-ALCL (Fig. 41.12). They may be multinucleate or resemble Reed–Sternberg cells. There is a background population of small lymphocytes, eosinophils, neutrophils, and histiocytes. Epidermotropism is variable but usually not prominent.

LyP type B is an uncommon pattern seen in 10% of cases.¹⁵ It is characterized by a perivascular or band-like dermal infiltrate with epidermotropism. The predominant cell types are small to medium-sized lymphocytes with cerebriform nuclei. This picture resembles plaque stage MF, and separation from MF may require clinical correlation. Large CD30⁺ cells seen in the other two forms are uncommon. Some lesions have overlap features of these two types. Different lesions in the same crop may show either of these patterns.⁶⁴⁵

LyP type C lesions resemble C-ALCL and have a monotonous population of large atypical cells with relatively few admixed inflammatory cells (Fig. 41.13A).

Figure 41.12 Lymphomatoid papulosis. (A) Type A histology. (B) There is a mixture of large atypical cells and small lymphocytes. (H&E)

Figure 41.13 Lymphomatoid papulosis. (A) Type C lesion showing a monotonous population of large atypical cells. (B) Type D lesion, in which there is marked epidermotropism of neoplastic cells. These cells express CD8 and CD30. (H&E)

LyP type D was described in 2010,⁶⁴⁶ with an additional case report appearing in 2012.⁶⁴⁷ This variant shows marked epidermotropism composed of neoplastic cells expressing CD8 and CD30 – a cytotoxic phenotype (Fig. 41.13B). Therefore, this variant simulates aggressive epidermotropic CD8⁺ T-cell lymphoma (see later).

LyP type E, a term first proposed by Kempf *et al.* in a 2013 publication,⁶⁴⁹ refers to an angioinvasive form of the disease. Clinically, there are often just a few papulonodular lesions that form larger ulcers; these evolve to hemorrhagic, necrotic crusts that spontaneously heal over 3–6 weeks. There may be recurrences, and smaller lesions more typical of *LyP* can also occur. Microscopic findings include infiltration and destruction of small to medium-sized dermal or subcutaneous vessels by atypical lymphoid cells; thrombosis and hemorrhage also occur.

A new subtype of *LyP*, reported in 2013 by Karai *et al.*, consisted of papulonodular lesions arising in elderly individuals and clinically resembling various inflammatory diseases or tumors.⁶⁵² Microscopic findings included epidermotropism and adnexal infiltration by small to

medium-sized cells with irregular nuclei resembling those of MF, with medium-sized to larger cells in the dermis. Immunostaining showed variable CD4 and CD8 expression, with biphasic CD30 positivity (strong and diffuse in the dermis, and weaker in the epidermis). The significant molecular finding on FISH analysis of the *DUSP22-IRF4* locus was a 6p25.3 rearrangement.⁶⁵²

Lesions in any of the subtypes may have focal spongiosis in the epidermis, parakeratosis with neutrophils, and ulceration. Epidermal hyperplasia is present in some cases.⁶⁵³ Mitotic figures are common in all histological subtypes. There is some dermal fibrosis in resolving lesions, particularly in those that have ulcerated. There may be only a few atypical cells in late lesions. CD1a⁺ dendritic cells may be a conspicuous component of the cellular infiltrate.⁶⁵⁴

A rare variant has been described in which the infiltrate is centered around hair follicles.⁶⁵⁵⁻⁶⁵⁷ Cases qualifying as type A, type B, overlapping type A/B, and type C have been described in follicular LyP.^{658,659} Findings include perifollicular infiltrates composed of CD30⁺ cells, often with follicular infiltration and follicular hyperplasia; occasionally, there are follicular rupture, follicular mucinosis, or intrafollicular pustule formation.⁶⁵⁹ Other variant patterns include a syringotropic pattern, LyP with epidermal vesicles, LyP with follicular mucinosis,⁶⁴⁵ LyP with prominent myxoid change,⁶⁶⁰ and LyP with angionecrosis.⁶⁶¹

Immunohistochemistry and cytogenetics

The large atypical cells in LyP types A and C are CD30⁺, CD3⁺, CD2⁺/-, CD4⁺/-, CD8⁻ similar to the large cells in C-ALCL. Rare cases are CD8⁺.^{662,663} Cells are generally negative for CD15 and EMA, but positive reactions have been reported in a few cases, the former having a cytoplasmic and Golgi zone pattern.⁵⁴³ As in C-ALCL, the CD30⁺ cells may express cytotoxic markers TIA-1, perforin and granzyme B, and CD56;^{565,663-666} they are ALK⁻.^{566,665}

The atypical cells in the type B lesions are CD3⁺, CD4⁺, CD8⁻. Despite some reports, CD30⁺ cells may be present in this subtype, and overlap cases with type A histology occur.^{15,645} The CD30⁺ cells may coexpress CD134.⁶⁶⁷

MUM1 is expressed in the large cells in types A and C.³¹⁸ One study found that there was positive staining for MUM1 in 85% of cases of LyP but only in 20% of cases of primary C-ALCL. It was suggested that this was a useful marker for distinguishing between these two conditions.⁶⁶⁸ Tumor necrosis factor receptor (TNFR)-associated factor 1 (TRAF1) has similarly been shown to be useful in distinguishing between LyP and C-ALCL, being expressed in 84% of the former and only in 7% of cases of anaplastic large cell lymphoma, primary and secondary.⁶⁶⁹

In type D LyP, there is marked epidermotropism in a pagetoid reticulosis-like pattern, often with associated acanthosis. The cells are CD30⁺ and have a cytotoxic phenotype – that is, β -F1⁺, CD3⁺, CD4⁻, CD8⁺ – with expression of at least one cytotoxic granule protein (TIA-1 and/or granzyme B). In occasional cases, the atypical cells are also CD56⁺.⁶⁴⁶ The infiltrating cells of type E LyP are CD30⁺ and CD8⁺, although there are also CD4⁺ cells in the angiocentric infiltrates; expression of TIA-1 is variable.⁶⁴⁹ In a minority of these cases, there are also CD56⁺ cells.^{649,650}

Clonal rearrangement of $\alpha\beta$ TCR genes has been identified in approximately 60% of lesions.^{641,670} No specific genetic abnormalities have been identified in LyP, and the t(2;5) translocation is not present. An example of LyP showing the $\gamma\delta$ T-cell phenotype has been reported.⁶⁷¹

Preliminary studies indicate concordance between reflectance confocal microscopy and histopathology in cases of LyP. Findings with reflectance confocal microscopy include surface refractile polygonal structures (parakeratosis); upwardly migrating, bright inflammatory cells, singly and in aggregates, obscuring of the dermal-epidermal junction; and infiltration of inflammatory cells in the upper dermis.⁶⁷²

Differential diagnosis

An accurate diagnosis of lymphomatoid papulosis depends on a combination of clinical features – recurrent, self-healing lesions, often in an otherwise healthy individual – with the typical microscopic findings. Although biopsy findings alone (including a wedge-shaped dermal infiltrate composed of atypical lymphocytes) may be highly suggestive, typical microscopic changes of lymphomatoid papulosis can occasionally be observed in cases that present clinically as solitary skin tumors – a picture more characteristic of C-ALCL. The clinical presentation of pityriasis lichenoides et varioliformis acuta (PLEVA) is quite similar to that of lymphomatoid papulosis, and the conditions share similar microscopic configurations (a wedge-shaped infiltrate and varying degrees of epidermal involvement and necrosis). Lymphocyte markers can be exploited in the differential diagnosis; for example, there are differences between the two disorders in degrees of CD8, CD79, and cutaneous lymphocyte-associated antigen expression, and of the two, CD30 expression is seen only in lymphomatoid papulosis.⁶⁷³ However, usually such detailed analyses are unnecessary because, in contrast to PLEVA, the cytologic atypia in lymphomatoid papulosis is profound. The Reed-Sternberg-like cells in type A lymphomatoid papulosis can raise the possibility of cutaneous Hodgkin's disease (see subsequent discussion). The history of recurrent, self-healing lesions would not be a typical one for Hodgkin's disease with cutaneous involvement. However, as previously noted, Hodgkin's disease can certainly evolve from lymphomatoid papulosis, and a histogenetic relationship between these disorders and anaplastic CD30⁺ lymphoma has been proposed.^{628,674} There may also be a rare primary cutaneous variant of Hodgkin's disease that presents with spontaneously regressing lesions. This condition differs from lymphomatoid papulosis in that the Reed-Sternberg cells are CD30⁺, CD15⁺, and CD45R⁻, whereas the morphologically similar cells of lymphomatoid papulosis are CD30⁺, CD15⁻, and CD45R⁺.⁶⁷⁵ Primary cutaneous ALCL usually lacks the wedge-shaped infiltrate and admixtures of inflammatory cell types of type A lymphomatoid papulosis, while displaying a higher percentage of CD30⁺ cells. However, the rare type C variant of lymphomatoid papulosis does show confluent sheets of CD30⁺ cells and could be difficult to distinguish from ALCL in the absence of clinical data. As mentioned previously, type D LyP has a close microscopic resemblance to aggressive epidermotropic CD8⁺ cytotoxic T-cell (Berti) lymphoma. Possible ways of distinguishing the two include CD45RA expression (found in Berti lymphoma and not LyP) and expression of T-cell receptor γ , often a feature of type D LyP.⁶⁷⁶

Berti lymphoma is typically negative for CD30; this should be a useful differentiating feature, except that false-negative staining for CD30 can occur in type D LyP, particularly in superficial biopsies where there has been inadequate sampling of the dermal component of the lesion.⁶⁷⁷ CD8⁺ MF often has a lesser degree of epidermotropism. Pagetoid reticulosis also has a CD30⁺, CD8⁺ phenotype, but the atypical infiltrate is confined to the epidermis and the clinical presentation (solitary plaque) is quite different from LyP. Another condition, indolent CD8⁺ lymphoid proliferation of the ear, differs by its lack of epidermotropism and the presence of a grenz zone separating the CD8⁺ dermal lymphocytic infiltrate from the overlying epidermis.^{676,678}

Type E LyP must be distinguished from angioinvasive T-cell lymphomas. The tumor cells of extranodal NK/T-cell lymphoma, nasal type are typically CD30⁻, and when CD30 is expressed in those tumors, it is rarely found in the majority of atypical cells. Furthermore, a link to EBV is found in most cases of extranodal NK/T-cell lymphoma, nasal type but not in cases of type E LyP.⁶⁴⁹ Cutaneous $\gamma\delta$ T-cell lymphomas, by definition, express TCR- δ , whereas examples of type E LyP are negative for this marker but positive for β -F1.⁶⁴⁹ The distinction from C-ALCL lesions that are angiocentric and have a CD8⁺

phenotype can be extremely difficult, requiring close follow-up for a history of self-healing lesions and recurrences.

SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA

The current WHO/EORTC classification confines this condition to those T-cell lymphomas that have a panniculitis-like histology and have an $\alpha\beta^+$ T-cell phenotype. This group previously included lymphomas with a $\gamma\delta$ phenotype. The latter group, which exhibits important differences in histology and behavior, is now classified separately as cutaneous $\gamma\delta$ T-cell lymphoma (provisional) in primary cutaneous peripheral T-cell lymphoma, unspecified of the WHO/EORTC classification.¹⁵ Most of the earlier literature does not distinguish between these two groups.⁶⁷⁹⁻⁶⁸² Other lymphomas can also involve the subcutis to varying degree.⁶⁸²

Most, if not all, cases of so-called cytophagic histiocytic panniculitis (see p. 540) in the older literature, particularly the indolent forms, are not inflammatory but, rather, subcutaneous panniculitis-like T-cell lymphoma (SPTCL).^{679,680}

This condition presents as single or multiple nodules and plaques mainly on the legs, but it may have a more general distribution. It can occur in the pediatric population.^{683,684} This lymphoma may be associated with systemic symptoms such as fever and weight loss or a hemophagocytic syndrome. The lesions usually do not ulcerate. It rarely presents as alopecia.⁶⁸⁵ Typically, there is an indolent course without extracutaneous spread.⁶⁸⁶⁻⁶⁸⁹ Cases complicated by a hemophagocytic syndrome have a more aggressive course.^{686,690} When the condition is carefully defined, the 5-year survival rate is approximately 80%.^{682,691}

Histopathology^{15,688,691}

The lymphomatous infiltrate is confined to the subcutis, where it predominantly involves lobules to produce a lobular panniculitis-like pattern (Fig. 41.14).⁶⁹¹ The atypical lymphocytes comprising the infiltrate are small, medium, or large with irregular hyperchromatic nuclei. Numerous histiocytes are also present. Granulomas may be present and can create diagnostic problems, particularly on fine needle aspiration cytology.⁶⁹² The atypical lymphocytes characteristically rim adipocytes to form a lace-like pattern, but this is not entirely specific.^{682,691} Apoptotic bodies (karyorrhectic nuclear fragments) are invariably present. A component of large phagocytic histiocytes ('beanbag histiocytes') containing cell debris or red blood cells (hematophagocytosis) is sometimes seen. Fat necrosis with foamy macrophages may also be present. In early stages of the disease, the cellular infiltrate may be less atypical.⁶⁸⁹ Plasma cells are present in some cases, but neutrophils and eosinophils are generally absent. Angiocentricity, angioinvasion, and large areas of necrosis are not typical of this entity. Several reports have described membranocystic lesions in the subcutis, consisting of thickened, undulating 'membranes' that line cystic spaces and form papillary configurations.⁶⁸⁷ These structures are believed to derive from degenerated cell membranes of lipocytes or macrophages, and they are composed of ceroid, an oxidation product of unsaturated fatty acids. Lipomembranous change is generally considered nonspecific, although it is prone to develop in forms of panniculitis associated with degrees of small vessel compromise. It is typical of SPTCL that the epidermis and dermis are spared. However, interface dermatitis, periadnexal inflammation and dermal mucin deposition can be identified, creating a striking resemblance to lupus erythematosus with panniculitis (see [Differential Diagnosis](#)).

Immunohistochemistry and cytogenetics

The neoplastic cells by definition have a TCR α/β , T-cell phenotype and are CD3⁺, CD45RO⁺, CD43⁺, CD4⁻, and CD8⁺. They also express

Figure 41.14 (A) Subcutaneous panniculitis-like T-cell lymphoma. (B) There are atypical lymphoid cells ringing adipocytes and histiocytes with cell debris. (H&E)

cytotoxic markers TIA1, perforin, and granzyme B. CD30 and CD56 are not expressed.¹⁵ The majority of cases are negative for EBV sequences by a variety of methods,⁶⁹³ but EBV genetic material has been found in some cases.^{694,695} Iwatsuki and associates suggest that EBV infection is detected in cases of SPTCL associated with hemophagocytic syndrome but is not identified in the uncommon, nonfatal cases labeled cytophagic histiocytic panniculitis.⁶⁹⁶

Recent genomic studies have shown that SPTCL is a uniform entity with characteristic gains of 5q and 13q as well as other abnormalities observed in cutaneous T-cell lymphoma types.⁶⁹⁷

TCR gene rearrangements are commonly identified.^{686,693} Testing for TCR monoclonality can be enhanced by microdissection techniques as a means of targeting specific cell populations.⁶⁹⁸

Differential diagnosis

The major considerations in the differential diagnosis of SPTCL are benign forms of panniculitis and other T-cell lymphomas that sometimes present with subcutaneous infiltrates. In addition to showing more polymorphous infiltrates and a lack of significant cytologic atypia, ordinary forms of panniculitis show mixtures of CD4⁺ and CD8⁺ T cells as well as CD20⁺ B cells.⁶⁹³ As previously noted, the resemblance to lupus erythematosus with panniculitis (lupus profundus) can be striking – so much so that some authors have proposed that the two

diseases can coexist, or that lupus erythematosus can evolve into SPTCL.⁶⁹⁹ This resemblance is also true of examples of $\gamma\delta$ T-cell lymphoma with subcutaneous involvement.⁷⁰⁰ Morphologic features that are said to aid in the distinction between lupus panniculitis and SPTCL (but are not entirely reliable) include lymphoid follicles, dermal mucin, limited cytologic atypia and adipocyte rimming, and hyaline fat necrosis (features more closely associated with lupus panniculitis) and fibrinoid/coagulative fat necrosis (SPTCL).⁷⁰¹ A recent report recommended human myxovirus resistance protein 1 (MxA) as a marker that can be used to differentiate between subcutaneous T-cell lymphomas and lupus panniculitis because the latter shows more extensive staining, both qualitatively and quantitatively, for this protein.⁷⁰² Clusters of plasmacytoid dendritic cells, identified by CD123 positivity, have been identified in the subcutaneous infiltrates of lupus panniculitis but not in SPTCL.⁷⁰¹ Other forms of peripheral T-cell lymphoma can involve the subcutis, but these are prone to also involve the epidermis and dermis, are likely to form solid sheets of tumor in preference to the rimming of individual lipocytes seen in SPTCL, and may show CD4 expression among neoplastic cells.⁶⁹³

As mentioned previously, lymphomas of the $\gamma\delta$ T-cell subtype can definitely involve the subcutis and, for a time, were included in the category of SPTCL. Although the immunohistochemical profile of these lesions overlaps with that of SPTCLs, $\gamma\delta$ T-cell lymphomas differ in that they are CD4⁺, CD8⁻, and CD56⁺.⁶⁸⁸ The majority of examples of SPTCL are not difficult to distinguish from extranodal NK/T-cell lymphomas, nasal type because the latter tumors have a predilection for sinonasal regions and are CD56⁺, CD8⁻, and EBV⁺. Extranodal NK/T-cell lymphomas, nasal type are perhaps more likely to involve the dermis as well as the subcutis, and they are particularly angiocentric.⁷⁰³ In addition, these lymphomas usually show a germline configuration of T-cell receptor genes.⁷⁰⁴ Both SPTCL and extranodal NK/T-cell lymphoma, nasal type are potentially aggressive tumors, although thus far extranodal NK/T-cell lymphomas involving the subcutis appear to be uniformly so, and they tend to be unresponsive to chemotherapy.⁷⁰³

EXTRANODAL NK/T-CELL LYMPHOMA, NASAL TYPE

NK and cytotoxic T cells are closely related in ontogeny and function, and they have overlapping immunophenotypic features.⁷⁰⁵

Extranodal NK/T-cell lymphoma, nasal type (E-NK/NT) is the best characterized of the NK/T group of lymphomas.^{508,706,707} The presence of EBV in almost all cases suggests a pathogenic role for this virus in the generation of this lymphoma. Rarely, there is documentation of preceding chronic active or continuous EBV infection.^{708,709} This form of lymphoma is common in Asia, South and Central America, and Mexico, but it is uncommon in the United States and Europe. It is almost always associated with EBV when carefully defined, even in white people.⁷¹⁰ Males are affected predominantly, with a median age in the fifth decade.⁷¹¹ Children and adolescents are rarely affected.⁷¹²

It presents most commonly in the nasal region, often with midline facial destructive disease ('lethal midline granuloma') or a nasal mass.⁷¹³ The extranasal form of this lymphoma presents most commonly in the skin and subcutis and less commonly in the upper respiratory tract, gastrointestinal tract, testis, and spleen.⁷¹¹ These organs are also the sites to which the nasal form most commonly disseminates.⁷¹⁴ Nasal metastasis may follow skin presentation.⁷¹⁵ Unlike lymphomatoid granulomatosis, the lung is rarely involved. Nodal involvement is also very uncommon,⁷¹⁶ although lymphadenopathy was found in 22% of patients in one study.⁷¹⁷

Cutaneous lesions include ulcerated tumors, subcutaneous nodules resembling a panniculitis, erythematous plaques, purpura, bullous

lesions, and a maculopapular rash.⁷⁰⁷ Lesions occur on the trunk and extremities.⁷¹⁸

A hemophagocytic syndrome is sometimes a complication. It may arise in a background of immunosuppression.⁷¹⁹ Neurolymphomatosis, producing peripheral neuropathy, is a rare manifestation of the disease and was the first indication of lymphoma in a recent case.⁷²⁰

This is an aggressive lymphoma with a short median survival and high mortality rate.^{710,721} In one series, the median survival was 5 months. Survival was slightly better when confined to the skin (median survival, 27 months).^{722,723} Some cases have overlap features with aggressive NK/T-cell leukemia.⁷¹⁰

An extremely rare intravascular variant has been described.⁷²⁴

Histopathology⁷²⁵

There is a diffuse or angiocentric and periappendageal cellular infiltrate that involves the dermis and subcutis (Fig. 41.15). The infiltrate consists of variably sized small and intermediate-sized lymphocytes. Large cells may predominate in some cases.⁷²⁵

Angiocentricity is associated with angioinvasion of vessel walls, sometimes with fibrinoid necrosis.⁵⁰⁸ Although this is common in this lymphoma, it is not always present;⁵⁰⁸ in a study of 73 patients from the M. D. Anderson Cancer Center, 31% lacked an angiocentric/angiodestructive growth pattern.⁷¹⁷ Furthermore, it is not a specific feature and can be seen in other cutaneous lymphomas, including B-cell neoplasms.⁷²⁶

Cellular pleomorphism may be slight, and this feature, together with a background population of other inflammatory cells including eosinophils and plasma cells, may lead to a misdiagnosis of an inflammatory reaction such as a lobular panniculitis.^{703,709,726} Involvement of the subcutis can mimic panniculitis-like T-cell lymphoma, particularly if angiocentricity is absent. Phagocytic macrophages and 'rimming' of adipocytes may be present.⁷⁰³

Zonal necrosis and karyorrhexis are frequently seen. This may be due to release of cytotoxic granules and the induction of apoptosis^{727,728} or to the production of TNF- α .

Epidermotropism is seen in some cases,⁷²¹ and pseudoepitheliomatous hyperplasia has been reported.⁷²⁹

Immunohistochemistry and cytogenetics

The tumor lymphocytes are CD56⁺, CD2⁺, and surface CD3⁻. They express cytoplasmic CD3 ϵ and the cytotoxic proteins TIA-1, perforin, and granzyme B. CD2, CD7, and CD8 are occasionally expressed.^{508,730} Small numbers of CD30⁺ cells are seen in some cases.^{709,731} EBV can be detected in most cases by *in situ* hybridization for EBER (EBV-encoded small RNA) and occasionally by immunohistochemistry (latent membrane protein-1 (LMP-1)).

There is no clonal rearrangement of the TCR (germline) in almost all cases. There can be clonal TCR gene rearrangement in rare cases with a cytotoxic T-cell phenotype.^{15,732} A related CD8⁺, CD30⁺, CD56⁺, CD3 ϵ ⁺, EBV⁺ aggressive neoplasm with clonal TCR gene rearrangement has been described.⁷³³ Adverse prognostic variables include a larger mean nuclear diameter of EBER⁺ tumor cells and CD30 positivity.⁷³⁴ In one study, high expression of LMP-1 and LMP-2A, encoded by EBV, correlated with a poor prognosis in patients with E-NK/NT.⁷³⁵ Expression of Trop2 (human trophoblastic cell surface antigen 2) indicates a more malignant phenotype and may also serve as an adverse prognostic factor.⁷³⁶

A variety of cytogenetic abnormalities have been reported; deletions of 6q are the most common.⁷²⁵

Differential diagnosis

The differential diagnostic possibilities in cases of cutaneous E-NK/NT include lymphomatoid granulomatosis and the lesion now termed

Figure 41.15 Extranodal NK/T-cell lymphoma, nasal type. (A) An angiocentric pattern of infiltration is evident. (B) A polymorphous lymphoid infiltrate is present in the wall of a vessel. (H&E)

blastic plasmacytoid dendritic cell neoplasm.^{731,737} Lymphomatoid granulomatosis has many morphologic and mechanistic similarities to E-NK/NT, including an association with EBV, but it is a peculiar angiocentric T-cell-rich B-cell lymphoma. The kidneys and central nervous system are also commonly involved by lymphomatoid granulomatosis but not by E-NK/NT.⁷³⁷ Blastic plasmacytoid dendritic cell neoplasm has an immunophenotype that differs slightly from that of E-NK/NT; it is characterized by variable positivity for CD2; reactivity for CD4, CD56, and CD123; and lack of expression of CD3, CD16, CD57, and EBV-related markers.^{738,739} Clinically, blastoid plasmacytoid dendritic cell neoplasm also differs in its pattern of systemic involvement, with regular involvement of multiple lymph nodes and the bone marrow. This disorder is currently believed to derive from precursors of plasmacytoid dendritic cells (see later discussion). Another potential diagnostic trap is the highly atypical, E-NK/NT-like lymphoproliferative response to herpesvirus infection.⁷⁴⁰ Although there is immunoreactivity for CD3, CD4, CD5, and CD56, studies for EBV infection are negative. The photosensitive, vesicular dermatosis known as hydroa vacciniforme also has a strong association with EBV infection and sometimes evolves into an NK/T-cell lymphoma. See further discussion of this condition later. Myeloid sarcoma shows positive staining for CD56, but it is also positive for CD34, CD33, myeloperoxidase, and lysozyme. Like SPTCL, E-NK/NT with subcutaneous involvement can display rimming of adipocytes by neoplastic cells; however, in contrast to the latter, SPTCL regularly expresses CD8 and cytotoxic granule proteins but is CD56⁻.⁷³³

Hydroa vacciniforme-like lymphoma

This is an EBV-related lymphoproliferative disorder of NK cells and rarely T cells that has overlap features with NK/T-cell lymphoma, nasal type and is considered by some a variant of that condition.⁷²⁵ Clinically, it mimics hydroa vacciniforme (see p. 623), an eruption related to sun exposure in which there are edema, vesicles, necrosis, and scars on the face and dorsa of the limbs.^{741,742} It is seen mainly in children from Asia⁷⁴³ or Central and South America, but it may also occur in adults.⁷⁴⁴

Clinically, there is a papulovesicular eruption on sun-exposed skin, particularly the face. The disease may be precipitated by insect bites. There may be associated systemic symptoms of fever and weight loss; lymphadenopathy and hepatosplenomegaly may be present. A hemophagocytic syndrome may occur.

The prognosis is said to be poor, but in some cases at least, it appears to be better than in typical E-NK/NT.^{725,745,746}

Histopathology

There are NK- or T-cell infiltrates that involve epidermis, dermis, and subcutis. There is frequent ulceration. As in E-NK/NT, there is commonly angiocentricity, angioinvasion, and necrosis.^{725,745}

Immunohistochemistry and cytogenetics

The cells are CD56⁺. The cells are variably reported as CD3⁺/-, CD4⁺/-, CD8⁺/-, CD30⁺/-, CD45RO⁺, and CD20⁻.^{745,747} TIA-1 is also positive.⁷⁴⁷ EBV is demonstrable in cells by EBER *in situ* hybridization.

There may be clonal TCR gene rearrangement, or the cells may be germline.^{745,748}

PRIMARY CUTANEOUS PERIPHERAL T-CELL LYMPHOMA, UNSPECIFIED

This heterogeneous group of cutaneous T-cell lymphomas does not fit into one of the well-defined subtypes of T-cell lymphoma.

Primary cutaneous aggressive epidermotropic CD8⁺ cytotoxic T-cell lymphoma

When carefully defined, primary cutaneous CD8⁺ epidermotropic cytotoxic T-cell lymphoma appears to be a clinicopathological entity distinct from classic MF, pagetoid reticulosis, and other cutaneous lymphomas that may have a CD8⁺ phenotype.^{386,749,750} It is characterized clinically by generalized patches, plaques, papulonodules, and tumors mimicking disseminated pagetoid reticulosis. There is systemic spread to the blood, lungs, testis, central nervous system, and oral cavity but not usually to lymph nodes.⁷⁵¹ It has an aggressive clinical course with a median survival of 32 months.^{41,386,751} A case has been described in an HTLV-1 carrier.⁷⁵² The status of those cases that appear to lack systemic involvement is unclear.⁷⁵³

Histopathology

In early lesions, there is an epidermal infiltrate of atypical lymphocytes in a pagetoid pattern. Fully developed lesions are characterized by a band-like dermal infiltrate of atypical cells as well as by diffuse infiltration of the epidermis. Atypical cells vary from small/medium to large pleomorphic cells and immunoblasts. The epidermis is acanthotic, and there are frequently secondary changes of spongiosis, vesiculation, and necrosis. Sweat gland and hair follicles are frequently involved, sometimes producing lymphoepithelial-like lesions. Rare eosinophils and plasma cells are present.

Immunohistochemistry and cytogenetics

The neoplastic lymphocytes have a CD3⁺, CD8⁺, CD7⁺, CD45RA⁺ phenotype and also express the cytotoxic markers TIA-1, granzyme B, and perforin. There is a high Ki-67 proliferation index. Unlike pagetoid reticulosis, these cases do not express HECA 452. Clonal rearrangement of the TCR- γ gene has been demonstrated in all cases. It is unclear whether the recently described case of aggressive epidermotropic CD4⁺/CD8⁻ cytotoxic T-cell lymphoma is a variant of this disease or a separate entity in the category of peripheral T-cell lymphomas.⁷⁵⁴

Differential diagnosis

Microscopically, primary cutaneous aggressive epidermotropic CD8⁺ cytotoxic T-cell lymphoma must be distinguished from at least three other conditions that have some overlap in microscopic features and a CD8⁺ phenotype, but with a much improved prognosis: pagetoid reticulosis (Woringer-Kolopp disease), type D lymphomatoid papulosis, and mycosis fungoides with a CD8⁺ positive phenotype,¹⁵ the latter being frequent in the pediatric age group.⁷⁵⁵ There can be some overlap in the appearance of the cutaneous lesions, although all three of these conditions tend to have a more chronic clinical course than aggressive epidermotropic CD8⁺ T-cell lymphoma, and the localized nature of pagetoid reticulosis is unique. The recurrences characteristic of lymphomatoid papulosis and the CD30 expression of its neoplastic T-cells help to distinguish this disorder from primary cutaneous aggressive epidermotropic CD8⁺ cytotoxic T-cell lymphoma.⁷⁵⁶ In addition, the latter is more apt to show invasion and destruction of adnexal structures as well as angioinvasion. Unlike MF, a diffuse epidermal infiltrate is still present in the tumor stage of aggressive epidermotropic CD8⁺ cytotoxic T-cell lymphoma.

Cutaneous $\gamma\delta$ T-cell lymphoma

This cutaneous lymphoma was previously regarded as a variant of SPTCL but has been separated from this group because of significant clinical and phenotypic differences.¹⁵ This form of cutaneous lymphoma presents as plaques, necrotic nodules, and tumors, particularly on the extremities. There may be involvement of mucosal and other

extracutaneous sites.⁷⁵⁷ A hemophagocytic syndrome may be present as in SPTCL.⁶⁹⁰ Unlike that form of lymphoma, there is usually an aggressive clinical course. In one series, the median survival was 15 months.⁷⁵⁸ Patients with involvement of the subcutis have a worse prognosis than those with more superficial disease. However, a more indolent form of the disease has also been described.^{759,760}

Histopathology

There is an infiltrate of medium to large atypical lymphocytes that may involve the epidermis, dermis, or subcutis, sometimes with angiotropism and necrosis.^{689,761} Ulceration is sometimes present. One case showed prominent epidermotropism soon after allogeneic stem cell transplantation.⁷⁶² Involvement of the subcutis resembles the pattern seen in SPTCL with 'rimming' of adipocytes. Apoptotic bodies are commonly observed.

Immunohistochemistry and cytogenetics

This lymphoma is a monoclonal proliferation of T lymphocytes that express the $\gamma\delta$ phenotype. This can be demonstrated by PCR on paraffin sections. Staining for TCR- δ (TCR- δ 1) by immunoperoxidase techniques can only be carried out on frozen section material.⁷⁵⁸ The cells are negative for β -F1 in paraffin sections, a marker for the $\alpha\beta$ phenotype, and now can be recognized by positive staining for TCR- γ , which is available for use in paraffin-embedded tissues.⁷⁶³ The atypical lymphocytes are CD3⁺, CD2⁺, CD56⁺ and also express cytotoxic markers such as TIA1 and granzyme B (Fig. 41.16). Most are CD4⁻ and CD8⁻, but occasional cases are CD8⁺.⁷⁵⁸ They are generally negative for EBV, but rare EBV⁺ cases have been reported from Asia.^{690,764}

A molecular study of one recent case showed highly complex cytogenetic abnormalities; it was suggested that significant genetic instability may contribute to the pathophysiology of this disease.⁷⁶⁵

Differential diagnosis

Cutaneous $\gamma\delta$ T-cell lymphoma must be distinguished from benign forms of panniculitis (see 'Subcutaneous panniculitis-like T-cell lymphoma' for discussion of this differential diagnosis). It should also be distinguished from SPTCL because of the somewhat better prognosis for the latter. The distinction is based on two major microscopic

Figure 41.16 Cutaneous $\gamma\delta$ T-cell lymphoma. This immunostain shows positivity for the cytotoxic granule protein T-cell intracellular antigen (TIA1) – a common finding in cutaneous $\gamma\delta$ T-cell lymphoma. (Immunohistochemical stain with antibody to TIA1)

considerations: (1) the frequent involvement of the epidermis and dermis as well as the subcutis in cutaneous $\gamma\delta$ T-cell lymphoma; and (2) differences in immunophenotype. The profile of SPTCL is CD3⁺, CD4⁺, CD8⁺, and β -F1⁺, whereas that for cutaneous $\gamma\delta$ T-cell lymphoma is CD3⁺, CD4⁺, CD8⁺ (with some exceptions), and β -F1⁺. A further means of distinguishing these two disorders is staining for TCR- γ , which would be positive in cutaneous $\gamma\delta$ T-cell lymphoma but negative in SPTCL. Note that TCR- γ can also be positive in other T-cell lymphomas, most notably MF and lymphomatoid papulosis, type D.⁷⁶³

Primary cutaneous CD4⁺ small/medium pleomorphic T-cell lymphoma

This rare lymphoma is defined by the presence of a cutaneous infiltrate of small to medium-sized T-lymphocytes that are CD4⁺, without pre-existing early lesions typical of MF. Cases with a CD8⁺ phenotype have also been reported⁷⁶⁶ but have been excluded from this category in the WHO/EORTC classification.¹⁵ The usual presentation is as a solitary plaque or tumor on the face, neck, or upper trunk, but less commonly multiple lesions may be present.^{767–769} The disorder can occur in children.⁷⁷⁰ The prognosis is usually excellent, particularly when there is a single nodule or localized skin involvement.^{3,767,769,771}

Histopathology⁷⁷⁰

There is a nodular or diffuse infiltrate in the dermis that may extend into the subcutis and, rarely, into the epidermis focally.¹⁵ The infiltrate is polymorphous and may mimic benign lymphoid hyperplasia. The predominant cells are small to medium pleomorphic T cells admixed with reactive B cells, plasma cells, and histiocytes (Fig. 41.17).⁷⁶⁷ Granulomas may be seen in the infiltrate.²⁷⁵

Immunohistochemistry and cytogenetics

The atypical T cells have a CD3⁺, CD4⁺, CD8⁺, CD30⁺ phenotype, and there may be loss of CD7 and CD2. The medium to large atypical cells express PD-1, bcl-6, and CXCL-13 (but not CD10) – markers characteristic of follicular helper T cells.⁷⁷² There is clonal rearrangement of TCR genes. This latter feature is useful in distinguishing this lymphoma from benign simulants or cutaneous B-cell lymphomas. However, see Differential Diagnosis.

Figure 41.17 Primary cutaneous CD4⁺ small/medium-sized pleomorphic T-cell lymphoma. There is a dense dermal infiltrate composed of small/medium-sized T cells, accompanied by reactive lymphocytes and histiocytes. (H&E)

Differential diagnosis

The major problem in primary cutaneous CD4⁺ small/medium-sized pleomorphic T-cell lymphoma is its distinction from reactive lymphoid infiltrates or other lesions that might be described as ‘pseudolymphomas’. This is the case because of the small size of many of the cells and the admixtures with reactive lymphocytes, macrophages, plasma cells, and eosinophils. Loss of pan-T-cell antigens, such as CD7 and CD2, and positive T-cell receptor gene rearrangement studies would certainly aid in this distinction. Ally *et al.* evaluated markers for follicular helper T cells in cases of CD4⁺ small/medium-sized pleomorphic T-cell lymphoma and in various forms of ‘dermatitis’ (including eczema, drug eruptions, and lupus erythematosus) and found significant differences between the two categories – for example, a higher percentage of PD-1⁺ and ICOS⁺ cells (ICOS is a marker for inducible T-cell co-stimulator) and rosette-like aggregates of PD-1⁺ cells in the lymphoma, but fewer of these cells and an absence of rosettes in dermatitis.⁷⁷³ In the study by Cetinozman *et al.*, all cases of primary cutaneous CD4⁺ small/medium pleomorphic T-cell lymphoma and cases labeled ‘cutaneous pseudo-T-cell lymphoma’ demonstrated positive staining for PD-1 (and other characteristics of follicular helper T cells), whereas this marker was only rarely expressed in other cutaneous T-cell lymphomas.⁷⁷² It appears that primary cutaneous CD4⁺ small/medium-sized pleomorphic T-cell lymphoma and lesions referred to as ‘cutaneous pseudo-T-cell lymphoma’ by Rijlaarsdam *et al.*⁷⁷⁴ have sufficient similarities in terms of clinical, morphologic, immunohistochemical, and T-cell gene rearrangement findings that they no longer deserve separate classification,⁷⁷² although the appropriate term that should be applied to these lesions remains open to discussion.

CUTANEOUS B-CELL LYMPHOMAS

Cutaneous follicle center cell lymphoma and extranodal marginal zone B-cell lymphoma of MALT type represent 90% of all forms of cutaneous B-cell lymphoma. They share similar clinical presentations, response to therapy, and an excellent prognosis.⁷⁷⁵

MARGINAL ZONE B-CELL LYMPHOMA

The majority of low-grade B-cell lymphomas appear to be of this type.^{776–778} The rubric *primary cutaneous marginal zone B-cell lymphoma* (PCMZL) also encompassed those lesions previously referred to as *cutaneous immunocytoma*^{779,780} and *cutaneous follicular hyperplasia with monotypic plasma cells*.⁷⁸¹ The current WHO/EORTC classification includes cutaneous plasmacytoma without underlying myeloma in this category because of overlap between this condition and plasma cell-rich lymphomas in this group (see p. 1207).¹⁵ European and British cases, but not those from the United States or Asia, may be associated with *Borrelia burgdorferi* infection.^{782–787}

This form of cutaneous lymphoma occurs most frequently in adults, with a male predominance.^{787–789} In one large series, the median age was 50 years, but there is a wide age range.⁷⁸⁸

Lesions occur predominantly on the arms and trunk,⁷⁸⁸ but many other sites, such as the head and neck, may also be involved.^{778,779,787,789–793} They are frequently multifocal, in contrast to primary cutaneous follicle center cell lymphoma. A dermatomal distribution has been described.⁷⁹⁴ This form of lymphoma can also involve the lip, tongue, and oral mucosa.⁷⁹⁵ The lesions are red to purple papules, nodules, and plaques. Lesions have a tendency to recur locally or at other skin sites, but dissemination to extracutaneous sites is very rare. These include lymph nodes and other sites, particularly other organs where MALT-type lymphomas occur.^{778,796} The lesions may spontaneously regress, sometimes leading to secondary anetoderma.⁷⁹⁷ Cases with a single

lesion or localized cluster of lesions are more likely to have a sustained complete remission than those with multiple nonlocalized lesions.⁷⁹⁸ The long-term prognosis is excellent, with a 5-year survival rate reported at 98%.⁷⁹⁹ Large cell transformation has been reported and is associated with a worse prognosis.^{39,800} Rarely, systemic spread leads to death.^{782,789,800} PCMZL has been reported with chronic lymphocytic leukemia,⁸⁰¹ with Hodgkin's lymphoma,⁸⁰² at the site of vaccination,⁸⁰³ and following fluoxetine therapy.⁸⁰⁴

Histopathology^{38,56,776,805}

There is a dermal cellular infiltrate that may extend into the subcutis but spares the epidermis. The infiltrate has a nodular or diffuse pattern characterized by reactive lymphoid follicles surrounded by paler zones containing a mixed population of cells that includes small lymphocytes, centrocyte-like cells with cleaved nuclei, monocytoid B cells with round nuclei and more prominent pale cytoplasm, lymphoplasmacytoid cells,⁸⁰⁶ and plasma cells. Where there is a more diffuse pattern, the mantles of follicles may be obliterated by the neoplastic component (follicular colonization).⁷⁸⁹ In the interfollicular areas, there are occasional large blasts as well as variable numbers of histiocytes and eosinophils. Plasma cells are often present at the periphery of the nodules or beneath the epidermis. Unlike the other extranodal marginal zone B-cell lymphomas (MALT lymphomas), lymphoepithelial lesions involving the skin appendages are rare but eccrine ducts or pilosebaceous units may be infiltrated by lymphoid cells.^{775,789,807} In cases previously reported as *immunocytoma*, there are often more diffuse infiltrates with few reactive follicles and more prominent lymphoplasmacytoid cells (lymphoid nucleus and plasma cell-like cytoplasm) and plasma cells (Fig. 41.18). Dutcher bodies (intranuclear periodic acid–Schiff-positive inclusions) may be present in these cells and are considered to be indicative of a neoplastic process. Lesions that consist overwhelmingly of monotypic plasma cells that have been called *cutaneous plasmacytoma* (see p. 1136) are also probably variants of cutaneous marginal zone B-cell lymphoma.⁸⁰⁸ Amyloid deposition has occurred in association with cutaneous marginal zone B-cell lymphoma.^{809,810}

Immunohistochemistry and cytogenetics

All variants of the small neoplastic cells express CD20 and CD79a. The latter is also expressed by plasma cells that also express CD38 and CD138. The lymphocytes also express bcl-2 but not CD5, CD10, CD43, cyclin D1, or bcl-6.⁷⁹² Plasma cells and lymphoplasmacytoid

Figure 41.18 Marginal zone lymphoma of MALT type. A reactive follicle is present with sheets of monotypic plasma cells. (H&E)

cells show cytoplasmic immunoglobulin light chain restriction. The scattered large blastic cells can be CD30⁺. Aberrant nuclear bcl-10 expression may be observed.^{787,811} Relapsed marginal zone B-cell lymphoma after treatment with rituximab has been associated with loss of CD20 expression.⁸¹²

Immunoglobulin heavy-chain (*IgH*) genes are clonally rearranged. Rare cases have shown a dual B- and T-cell phenotype.⁸¹³ A proportion of cases exhibit trisomy 3,⁸¹⁴ the t(14;18)(q32;q21) translocation, or the t(3;14)(p14.1;q32) translocation. These two translocations involve the *IGH* and *MALT1* genes and the *IGH* and *FOXP1* genes, respectively.^{815,816} The translocation involving *IGH* and *MALT1* is reported to be uncommon, however.⁸¹⁷ The t(14;18)(q32;q21) *IGH/BCL2* translocation has also recently been reported in PCMZL.⁸¹⁸ Frequent inactivation of *p15* and *p16* genes has been observed, most commonly as a result of promoter hypermethylation.⁸¹⁹

Differential diagnosis

The chief diagnostic problem in cutaneous marginal zone lymphoma is its distinction from reactive lymphoid infiltrates. Confirmation of an initial morphologic impression of marginal zone lymphoma can be obtained by identifying light chain restriction in tissues or by gene rearrangement studies. However, one should be aware of false-positive gene rearrangement studies, especially when current PCR-based methodologies are used. A combination of morphologic and immunohistochemical findings can usually permit distinction from other lymphomas involving the skin. The CD5 negativity of marginal zone lymphoma would allow its distinction from most mantle cell lymphomas, an uncommon lymphoma in skin (although a CD5⁺ mantle cell lymphoma in skin has been reported).⁸²⁰ Similarly, cyclin D1 expression is seen in mantle cell lymphoma but not in marginal zone lymphoma.⁸²⁰ A more difficult problem is the differentiation of marginal zone lymphoma from follicular lymphoma, another relatively common cutaneous B-cell lymphoma that has a follicular microscopic configuration (see later). However, the immunophenotypes of these two tumors are different in that primary cutaneous follicular lymphomas are bcl-6⁺, usually CD10⁺, and bcl-2⁻ (or only focally positive), whereas marginal zone lymphoma cells are bcl-6⁻, CD10⁻, and bcl-2⁺. Distinctive staining of the follicular structures of these two tumors can be demonstrated by identifying these antigens together with CD21, a marker for follicular mantle and dendritic cells.⁷⁹¹ A resemblance between cutaneous marginal zone lymphoma and B-cell chronic lymphocytic leukemia has also been noted. Both frequently produce nodular dermal infiltrates, and as with marginal zone lymphoma, cutaneous chronic lymphocytic leukemia can include plasma cells, which in a minority of cases show light chain restriction. Immunohistochemistry can be useful because marginal zone lymphoma, unlike chronic lymphocytic leukemia, does not express CD5 or CD43.⁸²¹

FOLLICLE CENTER CELL LYMPHOMA

Only comparatively recently has this low-grade primary cutaneous lymphoma been established as an entity that is distinct from conventional nodal follicular lymphoma^{38,528,791,822} and primary cutaneous marginal zone lymphoma.

Lesions that historically were called *reticulohistiocytoma of the dorsum*, *Crosti's lymphoma*, and *large cell lymphocytoma* are examples of this form of lymphoma.^{823–826} This is a lymphoma of adults; pediatric cases are extremely rare.⁸²⁷ It has been reported in a radiotherapy field.⁸²⁸ Most lesions arise on the head and neck and the trunk and are usually single, erythematous plaques or tumors. When on the trunk, there may be plaques or tumors surrounded by smaller papules. Multiple separate lesions do occur but are uncommon. The lesions can increase in size with time and recurrences are common, but extracutaneous spread is rare.^{827,829} The prognosis is excellent, with a 5-year

survival of 95%.^{830,831} The prognosis does not depend on whether the growth pattern is follicular or diffuse, or whether there is localized or multifocal skin disease.⁸³¹ There may be a worse prognosis in those with a diffuse large cell histology and strong expression of bcl-2.⁸³²

Histopathology

There is a nodular or diffuse infiltrate involving the dermis and sometimes the subcutis. The infiltrate may have a vertical orientation that is centered on skin appendages and neurovascular bundles.⁸³³ The infiltrate may rarely involve the subcutis only.⁸³⁴ There may be a follicular, follicular and diffuse, or a diffuse pattern. The last is distinct from other forms of large cell lymphoma, such as diffuse large cell lymphoma, leg type. A prominent follicular pattern is most typically seen in lesions from the head and neck (Fig. 41.19). Follicles are often variable in size and may fuse together.³⁸ Unlike reactive follicles, there is usually an absent or poorly developed mantle or fragmentation of the germinal center with invagination of the mantle zone resembling nodal progressive transformation of germinal centers. This has been referred to by some as a 'floral pattern'.⁸³³ The follicle centers contain varying proportions of large and small centrocytes with cleaved nuclei and centroblasts with noncleaved nuclei and

prominent nucleoli. The distribution of these cells lacks the polarization into predominantly centroblastic or centrocytic zones seen in reactive germinal centers. Tingible body macrophages are absent or few in number (Fig. 41.20). Occasionally, the follicle center cells have a spindled appearance. There are surrounding infiltrates of small lymphocytes sometimes with histiocytes, eosinophils, and plasma cells. The diffuse forms have sheets of large follicle center cells including large centrocytes, multilobated cells, and variable numbers of centroblasts and immunoblasts. Unlike other diffuse large cell lymphomas, the infiltrate does not consist of a monotonous population of centroblasts and immunoblasts.⁸³¹

The small number of spindle cell B-cell lymphomas reported in the literature probably represent variants of diffuse follicle center cell lymphoma because the tumor cells mostly resemble elongated and distorted large centrocytes.⁸³⁵⁻⁸³⁷ There may be associated myxoid change in the stroma.⁸³⁸

Immunohistochemistry and cytogenetics

The follicular pattern is emphasized by CD21 staining of follicular dendritic cells. Only ragged remnants of these cells are present as the pattern of infiltration becomes more diffuse. The neoplastic cells are

Figure 41.19 Follicle center cell lymphoma. The follicular structures may be large and irregular. (H&E)

Figure 41.20 Follicle center cell lymphoma. There is a poorly formed mantle zone and no tingible body macrophages. (H&E)

CD10⁺, CD20⁺, CD43⁺, CD79a⁺, and bcl-6⁺. CD10 and bcl-6 also demonstrate small groups of cells outside the germinal centers. Reactive T cells are present in follicles and interfollicular areas. MIB-1 usually reveals a low proliferation fraction in the follicle centers. Plasma cells are polyclonal. There is variable staining of the follicle center cells for bcl-2, but it is absent in most cases and, if present, may be only in a small proportion of cells, unlike follicular lymphoma of lymph nodes.^{38,790,791,839–842} A strong positive reaction raises the possibility of a secondary follicular lymphoma. A small number of cases are positive for MUM1.⁸⁴³

Clonal rearrangement of IgH can be demonstrated in more than 50% of cases.⁸⁴⁴ Unlike follicular lymphoma of lymph nodes, the t(14;18) translocation is not found in most cases.^{845,846} A comparatively recent study showed that in 41% of cases, the translocation t(14;18) was demonstrated by FISH techniques but in no cases by PCR.⁸⁴⁴ Mutations of the *BCL-6* gene have been detected.^{840,844}

Differential diagnosis⁸⁴⁷

The main differential diagnosis for both *primary cutaneous marginal zone B-cell lymphoma* (CMZL) and *cutaneous follicle center cell lymphoma* (FCL) is *cutaneous lymphoid hyperplasia* (LH). All have a follicular growth pattern in part. Separation of these conditions still remains difficult but can be achieved in most cases by a combination of histopathology, immunohistochemistry, and B-cell gene rearrangement studies.

Some histological features previously considered to be helpful in separating lymphoma from lymphoid hyperplasia are now known to be unreliable, such as ‘bottom heavy’ versus ‘top heavy’ cellular infiltrates.⁸³³ Although malignant infiltrates are more likely to be ‘bottom heavy’ and deep, often involving the subcutis, this pattern can also be seen in benign infiltrates.

In florid reactive lymphoid hyperplasia, the lymphoid follicles may have a poorly formed or absent mantle zone. Follicle centers in LH and CMZL tend to show zonation, have obvious tingible body macrophages, and have more centroblasts and immunoblasts. Follicle centers in FCL lack zonation, have a predominance of large cleaved centrocytes, and have no, or only rare, tingible body macrophages.

A useful immunohistochemical feature for distinguishing FCL from LH is the presence of small clusters of CD10⁺/bcl-6⁺ cells in the interfollicular zones in the former. There is a low MIB-1 proliferation fraction in FCL compared with LH. The follicle centers are predominantly negative for bcl-2 in all three conditions. Rare cases of FCL are positive for bcl-2 but must be distinguished from secondary nodal follicular lymphoma.⁸⁴⁷

The margins of the follicle centers, delineated by follicular dendritic cells demonstrated by CD21, tend to be well-defined in LH and CMZL and more irregular in FCL. Plasma cells in CMZL are monoclonal, and they are polyclonal in FCL and LH.

The presence or otherwise of other inflammatory cells such as histiocytes, plasma cells, and eosinophils is not helpful in separating these conditions.

PCR for IgH gene rearrangement has demonstrated monoclonality in approximately half the cases of the two forms of lymphoma but also in 10% of cases considered to be hyperplasias.

Immunohistochemical staining for IgM in paraffin-embedded sections is effective in distinguishing primary cutaneous follicular center cell lymphoma (usually negative) from primary cutaneous large B-cell lymphoma, leg type (consistently positive cytoplasmic staining for IgM, sometimes with coexpression of IgD). This result may indicate defective class switch recombination in this form of primary cutaneous large B-cell lymphoma.^{848,849}

Primary cutaneous spindle cell B-cell lymphoma of follicular center cell origin should be distinguished from other malignant spindle cell tumors, including spindle cell squamous cell carcinoma, spindle cell

melanoma, atypical fibroxanthoma, and soft tissue sarcomas. Distinction is facilitated by recognizing that rounded lymphoid forms are also present and by staining for B-cell markers, including CD20 and CD79a.⁸⁵⁰ The cells have also been bcl-6⁺, bcl-2⁺, and MUM1⁺.⁸⁵¹

DIFFUSE LARGE B-CELL LYMPHOMA

In the general WHO classification of lymphomas, diffuse large cell lymphomas are composed of large cells with nuclei at least twice the size of a small lymphocyte and usually larger than a macrophage nucleus (Fig. 41.21). Cell types include centroblasts or large noncleaved cells (cells with scant basophilic cytoplasm and round nuclei with multiple medium-sized, usually peripheral nucleoli) and also immunoblasts (large cells with more conspicuous, often amphophilic cytoplasm, oval nuclei, and a large single, central nucleolus). Other cell types include large centrocytes (large cleaved cells with small nucleoli), multilobated cells, and anaplastic large cells identical to T-cell and null-cell anaplastic lymphoma.¹ Nodal diffuse large B-cell lymphoma may present in the skin.^{852–854}

Vermeer *et al.*, and subsequently the authors of the EORTC classification, distinguished a form of diffuse large cell lymphoma that occurred predominantly on the leg – *large B-cell lymphoma of the legs*.⁸⁵⁵ This appears to be a distinct type of primary lymphoma that subsequently has been shown to occur at sites other than the leg.^{15,856} There are clinical, morphological, and immunohistological features that distinguish this lymphoma from the diffuse form of primary follicle center cell lymphoma that has histological features of a large cell lymphoma.

The concept of primary cutaneous diffuse large B-cell lymphoma, leg type has been controversial, but the current WHO/EORTC classification distinguishes this lymphoma as a specific subtype of diffuse large B-cell lymphoma. The remaining primary large B-cell lymphomas are classified under the rubric *primary cutaneous diffuse large B-cell lymphoma, other*. This group includes other rare cases of large B-cell lymphoma occurring in the skin, including *intravascular large B-cell lymphoma*, *T-cell rich/histiocyte-rich B-cell lymphoma*, and *anaplastic or plasmablastic types*.

Primary follicle center cell lymphoma with a diffuse large cell morphology is classified with that subtype.

In a study of cutaneous large B-cell lymphomas, 90.3% of cases could be classified as either primary cutaneous diffuse large B-cell lymphoma, leg type or primary cutaneous follicle center cell lymphoma.⁸⁴³ Both these lymphomas appear to be of germinal center origin.^{857,858} Gene expression profiling supports the subdivision of the two main types of cutaneous large cell lymphoma.^{27,859}

In both these groups, expression of bcl-2, OCT-2, and MUM1 is associated with a poor prognosis and staining with bcl-6 with a good prognosis.^{860,861} Location of primary cutaneous large cell lymphoma on the leg was an independent prognostic factor in some series.⁸⁶²

Genetic aberrations including numerical alterations were identified in 76% of cutaneous large B-cell lymphoma regardless of the type.⁸⁶³

DIFFUSE LARGE B-CELL LYMPHOMA, LEG TYPE

Although this lymphoma occurs most frequently on the legs (72% in one series),⁸⁶⁴ tumors with identical features can occur at other sites. It is a tumor of the elderly (mean age, 76 years), with a female predominance of cases.⁸⁶⁴ It has been reported in a background of chronic lymphedema of the leg or chronic venous insufficiency.^{843,865,866} The classic presentation is of one or more rapidly growing erythematous tumors on one or both lower legs; ulceration is common. Occasional lesions are annular.⁸⁶⁷ One case was preceded by a hemophagocytic syndrome.⁸⁶⁸ The lesions relapse frequently after therapy, and extracutaneous spread is common. In a comparatively recent study, the

Figure 41.21 (A) Diffuse large B-cell lymphoma. (B) The large B cells are predominantly centroblasts and immunoblasts. (H&E)

overall 5-year disease-specific survival rate was 41%. In this series, the central nervous system was the most frequent site of visceral dissemination.⁸⁶⁴

Relapse as an intravascular large B-cell lymphoma has been reported.⁸⁶⁹ The clinical, histopathological, and immunophenotypic features of primary cutaneous diffuse large B-cell lymphoma, leg type are identical to those of testicular B-cell lymphoma with secondary cutaneous involvement.⁸⁷⁰

Histopathology

There is a diffuse infiltrate in the dermis and frequently the subcutis of large lymphocytes with the features of centroblasts and immunoblasts. Mitotic figures are common. Other cellular elements are uncommon. The cells usually have round nuclei and lack the cleaved appearance of the predominant large lymphocytes seen in primary follicle center cell lymphoma.

Immunohistochemistry and cytogenetics

The cells are CD20⁺, CD79a⁺, and bcl-6⁺. Most express bcl-2 and MUM1/IRF4,⁸⁶⁴ unlike cutaneous follicle center cell lymphoma. Interestingly, MUM1/IRF4 expression in these tumors is not associated with IRF4 gene rearrangement or amplification.⁸⁷¹ Some cases also

express FOX-P1 (a member of the FOX-P transcription factors).⁸⁴³ A minority of cases express CD10.⁸⁴³ Rare cases are CD30⁺.^{843,872}

The tumor is not generally associated with EBV or HHV-8.^{843,873} However, in a recently reported case, HHV-6 and HHV-8 were found in nucleoli of neoplastic cells using immunohistochemical methods.⁸⁷⁴

Treatment of B-cell lymphomas including large B-cell lymphoma, leg type with rituximab (an anti-CD20 monoclonal antibody) therapy may result in recurrences failing to stain for CD20, a potential pitfall for dermatopathologists.⁸⁷⁵⁻⁸⁸² In this situation, staining for Pax5, a pan B cell marker, may be useful.⁸⁸³

The tumor cells exhibit hypermutations of the immunoglobulin genes and mutations of the *BCL-6* gene.⁷⁹⁵ The t(14;18) translocation is not present.^{884,885} A t(8;14) translocation has been identified in some cases.⁸⁸⁶

Somatic mutation of the myeloid differentiation primary response gene 88 (*MYD88*) gene is a feature of this type of lymphoma. The *MYD88* gene encodes a protein that plays a key role in the innate and adaptive immune response and is essential in the IL-1 and toll-like receptor signaling pathways. Mutations of this gene are found in 29% of nodal diffuse large B-cell lymphomas of the 'ABC' type – indicative of post germinal center-activated B-cell stages of B-cell differentiation.⁸⁸⁷

DIFFUSE LARGE B-CELL LYMPHOMA, OTHER

The best defined lymphoma in this group is intravascular large B-cell lymphoma, and it is given a separate designation in the WHO/EORTC classification. Other diffuse large cell lymphomas include anaplastic and plasmablastic subtypes, T-cell/histiocyte-rich large B-cell lymphomas, and other less well-defined entities.

Intravascular large B-cell lymphoma

Intravascular large B-cell lymphoma (IVLBL) is a rare form of lymphoma that commonly presents with skin lesions or pain. It has been termed ‘*intravascular lymphomatosis*’ and ‘*angiotropic large cell lymphoma*’.^{888,889} It is characterized as an intravascular proliferation of large atypical lymphoid cells. In the majority of cases, they are B cells, but rare cases with a similar histological appearance have a T- or NK-cell phenotype.^{890–893} It has been suggested that the lack of expression of CD29 (β_1 integrin) and CD54 (ICAM-1) adhesion molecules by the lymphoma cells is responsible for the disseminated intravascular pattern, these molecules being important in lymphocyte trafficking and transvascular migration.⁸⁹⁴

The median age at presentation is 70 years, and there is an approximately equal sex incidence.⁸⁹⁵

Cutaneous lesions are the dominant presenting feature in a third or more of cases.⁸⁹⁵ They take the form of erythematous to blue macules, plaques, and nodules^{896–899} and generalized telangiectasia.⁹⁰⁰ In some cases, there is only very subtle figurate erythema. Skin lesions may mimic panniculitis such as erythema nodosum,⁹⁰¹ hemangiomas,⁹⁰² angiolipomas,⁹⁰³ Kaposi’s sarcoma,⁹⁰⁴ thrombophlebitis, or erysipelas.⁸⁹⁸

Lesions occur predominantly on the upper and lower limbs and the trunk.⁸⁸⁵ Pain and ankle edema may accompany the skin lesions.

A subgroup of patients representing approximately 26% of cases, and who are invariably female, present with cutaneous manifestations only.⁸⁹⁵ Approximately one-third of cases present with neurological symptoms⁸⁹⁵ including a variety of motor and sensory deficits and dementia.^{895,905} Other presentations include disseminated intravascular coagulation⁹⁰⁵ and, almost exclusively in Asian countries, a hemophagocytic syndrome.^{906,907} Patients in this group rarely exhibit involvement of the skin or central nervous system. There is commonly an elevation of lactic dehydrogenase serum levels and anemia.⁹⁰⁸ Hepatosplenic and bone marrow involvement is common, but nodal involvement is rare.⁸⁹⁵

There may be an associated extravascular large cell lymphoma, either nodal or extranodal.^{909,910} There is a report of diffuse large B-cell lymphoma (diagnosed on splenectomy) with early recurrence showing intravascular lymphoma on a random skin biopsy.⁹¹¹ There are also reports of an association with follicular lymphoma and MALT lymphoma.^{894,912}

The prognosis is poor: 85% have a fatal outcome. The prognosis is better in those with disease restricted to skin; 10% have a fatal outcome in this group.^{898,913,914}

Histopathology

Blood vessels in the dermis and subcutis are partially or completely occluded by large atypical lymphoid cells (Fig. 41.22). The cells are several times larger than endothelial cells and have a high nuclear:cytoplasmic ratio. Nuclei are round to oval, and nucleoli are often prominent. Mitotic figures, including atypical forms, are frequently seen. Fibrin thrombi are often present in vessels, either with or without atypical cells. Extravascular neoplastic cells may also be found in up to 20% of cases.³ Occasionally, associated perivascular inflammatory changes may mask the intravascular lymphoma.⁹¹⁵

The upper dermis may be spared, and a superficial biopsy may not show the diagnostic changes.⁹¹³ On the other hand, a ‘blind’ biopsy of

Figure 41.22 (A) Intravascular large B-cell lymphoma. (H&E) (B) The intravascular cells are positive for CD20. (Immunoperoxidase stain for CD20)

apparently normal skin may show diagnostic changes.^{910,916,917} Random skin biopsy may be particularly useful in patients with neurologic symptoms, erythrocytopenia, elevation of lactate dehydrogenase and soluble IL-2 receptor, and absent nodal involvement.⁹¹⁸

Immunohistochemistry and cytogenetics

The atypical lymphocytes are CD20⁺, CD79a⁺, and CD3⁻. There is variable staining for CD5 (38%), CD10 (13%), bcl-6 (26%), MUM1 (95%), and bcl-2 (91%).⁹¹⁹

Monoclonal IgH rearrangements have been demonstrated by PCR on paraffin-embedded tissue.⁹²⁰ Rare cases are EBV⁺.⁹²¹

Differential diagnosis

The main differential diagnostic consideration is the exclusion of other intravascular tumors, including metastatic malignancies. The correct diagnosis of intravascular IVLBL relies on the identification of tumor cells as lymphocytes by immunohistochemical methods. This is also important in the distinction from reactive angioendotheliomatosis. The latter is composed of bland-appearing intravascular cells. Despite the occasional presence of factor VIII-related antigen in intravascular IVLBL, the neoplastic cells of intravascular lymphoma regularly express leukocyte common antigen (CD45) and B-cell (or, rarely, T-cell) antigens and are negative for CD31, *Ulex europaeus* lectin,

or blood group isoantigens. The reverse is the case in reactive angioendotheliomatosis.

Plasmablastic lymphoma

Plasmablastic lymphoma is a rare B-cell lymphoma most often, but not invariably,⁹²²⁻⁹²⁴ associated with HIV/AIDS or other forms of immunosuppression, such as organ transplantation.^{925,926} It may take an oral form or be associated with multicentric Castleman's disease (see p. 1139).⁹²⁷ It is associated with both EBV and HHV-8 infection.

Skin involvement alone is uncommon. In the skin, there are solitary or multiple, purple-red nodules or tumors that may ulcerate.^{928,929} The extremities are most commonly involved.⁹³⁰ Apart from the oral cavity, other common sites of involvement include the bone, soft tissues, and gastrointestinal tract.

It has an aggressive clinical course, with a median survival of 7 months in one series.⁹³¹

Histopathology⁹³¹

There is a diffuse infiltrate of medium-sized to large atypical cells in the dermis and subcutis with sparing of the epidermis. The cells have an eccentric, round nucleus with clumped chromatin and a central prominent nucleolus. Cytoplasm is abundant and basophilic. Apoptotic bodies and mitotic figures are frequent. Cells resembling maturing plasma cells are also present.

Immunohistochemistry and cytogenetics

The tumor cells are CD45⁺, CD38⁺, CD138⁺, CD20⁺, CD3⁺, CD5⁺, CD30⁺, bcl-6⁺, and Pax5⁺. There may also be monotypic cytoplasmic staining for immunoglobulin light chains.

The tumor is strongly associated with EBV, and the cells are positive for EBER. The cells may also be positive for HHV-8 by immunohistochemistry.

T-cell/histiocyte-rich B-cell lymphoma

Primary cutaneous T-cell-rich/histiocyte-rich B-cell lymphoma is a very rare variant of large B-cell lymphoma that is characterized by the presence of small numbers of neoplastic large B cells surrounded by large numbers of reactive small T cells and histiocytes.⁹³²⁻⁹³⁴ The relative proportions of large B cells and reactive T cells have not been clearly defined.⁹³⁵ The nodal form of this lymphoma rarely involves the skin secondarily.^{936,937} The average age of patients in several series was 42 years. The lesions have no particular anatomical distribution.⁹³⁸ It may be associated with HIV infection.⁹³⁵ An angiocentric form has been described that has similarities to lymphomatoid granulomatosis (see later).⁹³⁸ The clinical course is variable in the small number of cases described; some cases have progressed to disseminated disease.

Histopathology

Diagnosis is difficult because of the polymorphous nature of the infiltrate and the small number of neoplastic cells. There are scattered large B cells that may resemble centroblasts, immunoblasts, or Reed-Sternberg-like cells.⁹³³ The majority of cells are small lymphoid cells with variable numbers of histiocytes, eosinophils, and plasma cells. The differential diagnosis includes Hodgkin's lymphoma, peripheral T-cell lymphoma, and benign lymphoid hyperplasia.

Immunohistochemistry and cytogenetics

Diagnosis requires demonstration of a monoclonal population of B cells by PCR for IgH rearrangements or other techniques. The neoplastic B cells are CD20⁺, CD79a⁺, and positive for other pan-B-cell markers. Some are bcl-2⁺.⁹³⁹ The background lymphocytes are predominantly small T cells that are CD3⁺.

Lymphomatoid granulomatosis

The concept of lymphomatoid granulomatosis (LG) has evolved since it was first described by Liebow *et al.* in 1972.⁹⁴⁰ It was originally defined as an angiocentric, angiodestructive, lymphohistiocytic disorder that affected the lungs predominantly but had frequent extrapulmonary manifestations. It was for some time considered to be a T-cell proliferative disorder because of the large number of T cells in the lesions, although most studies failed to demonstrate a clonal proliferation of T cells.⁹⁴¹

EBV was identified in most pulmonary cases and some cutaneous lesions, implicating it in the pathogenesis of LG.^{942,943} Subsequent studies have localized EBV to a population of large atypical cells that may only represent a minor component in the polymorphous infiltrate.⁹⁴⁴⁻⁹⁴⁶ PCR studies have subsequently demonstrated a monoclonal B-cell proliferation.

LG is now regarded as an EBV-driven disorder of B cells with accompanying reactive T cells and histiocytes.^{946,947} There is a spectrum of histological grade⁹⁴⁸ and clinical behavior that reflects the proportion of large EBV-infected neoplastic B cells. Grade 3 lesions, in which the large B-cell proliferation is obvious, are regarded as diffuse large B-cell lymphoma.¹ Chemokines have been implicated in the vascular damage.⁹⁴⁹

Skin lesions are found in 40–60% of cases; they may be the presenting complaint⁹⁵⁰⁻⁹⁵⁵ and precede other manifestations by years. They take the form of erythematous or violaceous nodules or plaques that may be widely distributed on the trunk and lower extremities.⁹⁵¹ Rarely, paranasal or ulcerated palatal lesions are present. Any of the lesions may become ulcerated with eschar formation: this is more common with nodules on the leg.

The lung is the most commonly affected organ. The kidneys, liver, and central and peripheral nervous systems may also be affected, although the skin is the most common extrapulmonary site.^{940,956,957}

Many patients when investigated are found to have defects in cytotoxic T-cell function and reduced numbers of CD8⁺ T cells. Consequently, LG occurs in patients with immunodeficiency states such as HIV/AIDS, Wiskott-Aldrich syndrome, and following organ transplantation.⁹⁴⁹ There are overlap features with *post-transplant lymphoproliferative disorders* (PTLD) because both are B-cell lymphoproliferative disorders associated with EBV. The infiltrates of PTLD are 'T-cell poor' compared to the T-cell-rich infiltrates of LG.⁹⁵⁸

LG has been reported in association with imatinib therapy, which can inhibit T-cell receptor-mediated T-cell proliferation and activation,⁹⁵⁹ and complicating other hematologic neoplasms associated with abnormalities of T-cell function.⁹⁶⁰

Onset is usually in early middle age: it has rarely been reported in children.⁹⁶¹ In older studies, there was a rapid downhill clinical course, with a median survival of 14 months.⁹⁵⁶ Death was usually from respiratory failure often associated with the development of an overt large B-cell lymphoma in the lungs.⁹⁴⁷ Currently, longer survivals have been reported with multiagent chemotherapeutic and interferon therapy.^{941,944} Spontaneous regression of lesions may occur.⁹⁴¹

Histopathology

There is a polymorphous proliferation with perivascular, periappendageal, and perineural accentuation.⁹⁵⁰ Sweat glands are particularly involved.⁹⁵³

The infiltrate is composed of a mixture of small lymphocytes and a variable number of large lymphocytes with vesicular nuclei and prominent nucleoli that may resemble immunoblasts; some multinucleate forms resemble Reed-Sternberg cells.^{941,951} These cells are absent or rare in grade 1 lesions, are more prominent in grade 2 lesions, and form a major part of the infiltrate in grade 3 lesions that have features of diffuse large B-cell lymphoma. There are variable numbers of reactive histiocytes and eosinophils; neutrophils are present in ulcerated

Figure 41.23 Lymphomatoid granulomatosis. There are granulomas in the infiltrate in this case. (H&E)

Figure 41.24 Lymphomatoid granulomatosis with many large, atypical lymphocytes in the wall of a vessel. (H&E) The inset shows positive staining of lymphocytes with EBV *in situ* hybridization.

lesions. Occasionally, granulomas are present in skin lesions despite reports to the contrary in the lung literature (Fig. 41.23). In addition to being angiocentric, the infiltrate is angioinvasive. Both arteries and veins may be affected. Cells invading vessel walls are predominantly small lymphocytes and histiocytes with fewer large atypical cells in low-grade lesions (Fig. 41.24).⁹⁴¹ Large atypical cells and fibrinoid necrosis of the vessel wall are seen in higher grade lesions. Tissue necrosis is sometimes conspicuous in higher grade lesions. Marked fibroblastic proliferation may also be present.

Sometimes the histology of skin lesions may not be diagnostic, despite the presence of typical changes in other organs.

Immunohistochemistry and cytogenetics

The neoplastic cells are B cells and are CD20⁺, sometimes CD43⁺, and CD3⁻. They are variably positive for CD30. The atypical B cells are EBV⁺. EBER can be demonstrated by *in situ* hybridization techniques.⁹⁴¹

EBV⁺ cells, like atypical large B cells, are few or absent in grade 1 lesions, which may make the diagnosis difficult. EBV⁺ cells are said to be less frequently identified in skin lesions than lung lesions. Clonal rearrangement of immunoglobulin heavy chain gene can be demonstrated in some cases.⁹⁴¹ The T cells are CD3⁺, and CD4⁺ cells predominate over CD8⁺ cells.

Differential diagnosis

Those cases with polymorphic infiltrates can be confused with benign forms of lymphocytic vasculitis, a term applied to a heterogeneous group of reactive conditions characterized by infiltration of vessel walls by lymphocytes and, less commonly, fibrinoid necrosis of vessels. Examples of lymphocytic vasculitis include pityriasis lichenoides, forms of pigmented purpura, perniosis, and certain infectious exanthems. These conditions can generally be excluded by clinical data or by findings on routine microscopic study. In particular, they tend to show more superficial dermal infiltrates than would be the case for LG. In the inflammatory conditions characterized by lymphocytic vasculitis, infiltrates tend to be mild to moderate, and cytologic atypia is minimal. Furthermore, B-cell clonality would not be demonstrable (although T-cell receptor gene rearrangements have been identified in cases of pityriasis lichenoides, and at least some examples of pigmented purpura may represent a form of T-cell lymphoid dyscrasia). More granulomatous examples of LG may bear a resemblance to Wegener's granulomatosis (WG), which only displays the classic combination of necrotizing granulomatous inflammation and a necrotizing vasculitis in a minority of cases (see p. 271). Atypical large lymphocytes are not seen in WG, but they may also be absent in low-grade lesions of LG. Neutrophils are not usually seen in LG without necrosis and ulceration. The presence of a largely histiocytic infiltrate with a perineural distribution may also mimic leprosy on biopsies.⁹⁵¹ The angiocentricity of LG is similar to that of extranodal NK/T-cell lymphoma, nasal type, and in fact these disorders were formerly linked. Both are associated with EBV. However, extranodal NK/T-cell lymphoma, nasal type has a predilection for sinonasal and nasopharyngeal tissues; is a lesion composed of NK/T cells that mark CD2⁺, CD56⁺, and CD3ε⁺; and it is positive for cytotoxic granule proteins. In high-grade lesions of LG, the more numerous (and therefore more apparent) atypical lymphoid cells resemble those of Hodgkin's disease. However, cutaneous involvement in Hodgkin's disease is rare, and angiocentricity is not characteristic. Classic Reed–Sternberg cells are not identified in LG. In addition, the atypical B cells of the latter disorder are negative for CD15.⁹⁶² One example of a post-transplant lymphoproliferative disorder involving the skin had the microscopic characteristics of LG.⁹⁵⁸

CD30⁺ large B-cell lymphoma associated with EBV

There are rare cases of cutaneous diffuse large cell lymphoma that stain positively for B-cell markers (CD20, CD79a), CD30, and EBV that do not fall into other defined entities in this group.^{963–965}

PRECURSOR HEMATOLOGIC NEOPLASM

Only one entity is considered under this heading.

Blastic plasmacytoid dendritic cell neoplasm

The previous designation of this rare entity had been CD4⁺/CD56⁺ *hematodermic neoplasm* (*blastic NK-cell lymphoma*), but it has been changed to blastic plasmacytoid dendritic cell neoplasm in the most recent WHO classification because the neoplastic cells share the markers for plasmacytoid dendritic cells.^{738,966–970} It was originally defined as an acute leukemia or cutaneous neoplasm that coexpressed

CD4 and CD56 without specific markers for myeloid, B, T, or NK cells. Because skin involvement usually precedes a leukemic phase, it may represent a form of aleukemic leukemia cutis derived from precursor cells.⁹⁷⁰

It most commonly affects adults (median age, 67 years), with a male:female ratio of 2:1.⁹⁶⁸ It has also been reported in children and adolescents.^{971–974}

It presents as skin lesions in 90% of cases, but there is rapid spread systemically to many other sites, including blood, bone marrow, lymph nodes, spleen, liver, and the central nervous system.^{966,969,975–978} Skin lesions may be localized or disseminated and take the form of erythematous or bruise-like, red or purple patches, papules, nodules, and tumors.

This is an aggressive neoplasm with a poor prognosis. The median survival is 14 months.⁷²² Children and those who present with only skin lesions may have a slightly better prognosis.^{722,971}

Histopathology^{15,966,969}

There is an infiltrate of uniform medium-sized cells with little cytoplasm and nuclei with finely dispersed chromatin and inconspicuous nucleoli in the dermis and/or subcutis (Fig. 41.25). The cells resemble myeloblasts or lymphoblasts. The epidermis is not involved, and there is usually no necrosis, angioinvasion, or inflammatory cells in the infiltrate. ‘Rimming’ of adipocytes can be seen where the subcutis is infiltrated.⁶⁹¹

Immunohistochemistry and cytogenetics

This lesion was initially defined by the coexpression of CD4 and CD56, but this neoplasm can express markers of other lineages. The cells usually have a CD4⁺, CD56⁺, CD8⁻, CD2^{+/−}, CD7^{+/−}, CD45RA⁺ phenotype and are negative for CD3 and cytotoxic markers.^{966,979} The cells also express CD123 (the IL-3R α chain), a marker of plasmacytoid dendritic cells,^{980,981} TCL1 (lymphoid proto-oncogene),⁹⁸² BDCA-2 (CD303; an immature dendritic cell marker), CD2AP, and the B-cell-associated transcription factor BCL11A.^{983,984} CD68, TdT (terminal deoxynucleotidyl transferase), and CD43^{968,982,985} are sometimes expressed.⁷²² CD56[−] cases have been reported.⁹⁷⁹ Weak staining for CD33, a myeloid marker, has also been described.⁹⁷⁹ A rare, related condition – acute myeloid (or type 1) dendritic cell leukemia – may

present in the skin. In this condition, myeloid markers are expressed as well as CD4, CD56, and CD123.⁹⁸⁶

Loss of CD56 expression has been recorded in a relapsed tumor that followed treatment with chemotherapy and bone marrow transplantation.⁹⁸⁷

The TCR genes are usually germline, but a rare variant with a T-cell gene rearrangement has been described.⁹⁸⁸ Tumor cells are negative for EBV.

Cytogenetic studies have revealed an abnormal complex tumor cell karyotype with frequent deletions of 5q.^{969,979}

Differential diagnosis

An initial resemblance of cutaneous microscopic findings to those of lupus erythematosus (epidermal atrophy, necrotic keratinocytes, swollen collagen bundles, and a mixed lymphohistiocytic infiltrate) has been described; subsequent cutaneous and bone marrow immunohistochemical analysis led to the correct diagnosis of blastic plasmacytoid dendritic cell neoplasm in this case.⁹⁸⁹ There can be a morphologic resemblance to other lymphomas and leukemias. Regarding immunohistochemical staining, expression of CD56 can also be seen in extranodal NK/T-cell lymphoma, nasal type and cutaneous $\gamma\delta$ T-cell lymphoma, and TdT expression is characteristic of precursor T (as well as precursor B) -lymphoblastic lymphoma. Distinction can be made by the expression of plasmacytoid dendritic antigens in blastic plasmacytoid dendritic cell neoplasm and the usual negativity for EBV antigens or EBV-encoded small nuclear RNA, in contrast to the positivity for EBV associated with NK/T-cell lymphoma, nasal type. As noted previously, cutaneous lesions composed of plasmacytoid dendritic cells can be associated with acute myeloid leukemia. As is the case for the neoplastic cells in blastic plasmacytoid dendritic cell neoplasm, the cells in the latter condition express CD123, CD4, and TCL1. Among the microscopic differences, the plasmacytoid dendritic cells associated with myeloid leukemia form aggregates that are demarcated from the leukemic cells; they are small to medium-sized cells with rounded to oval nuclei and fine chromatin. The cells of blastic plasmacytoid dendritic cell neoplasm are morphologically similar but are medium- to large-sized and not associated with leukemic cells. In terms of immunohistochemical differences, the cells of blastic plasmacytoid dendritic cell neoplasm are regularly CD56⁺ and sometimes express TdT, whereas those in lesions associated with myeloid leukemia are CD56[−] and TdT[−].⁹⁸⁴ There are also considerable clinical and morphologic similarities between myeloid sarcoma involving the skin and cutaneous blastic plasmacytoid dendritic cell neoplasm. Positive staining for myeloperoxidase of lysozyme and negative staining for CD56, CD123, TCL1, and MxA point to a diagnosis of myeloid sarcoma with a high degree of reliability, whereas positivity for CD56, TdT, or TCL1 and negative staining for lysozyme indicate a diagnosis of blastic plasmacytoid dendritic cell neoplasm.⁹⁹⁰

Figure 41.25 Blastic plasmacytoid dendritic cell neoplasm. There is a diffuse dermal infiltrate of blastic cells. (H&E) The cells are monotonous (lower inset); they are CD56⁺. (Top inset, immunoperoxidase stain)

OTHER T/NK-CELL LYMPHOMAS THAT MAY INVOLVE THE SKIN

This group of lymphomas is not included with the other primary cutaneous lymphomas.

PRECURSOR T-LYMPHOBLASTIC LEUKEMIA/LYMPHOMA

This leukemia/lymphoma rarely presents in the skin and does so much less commonly than its B-cell counterpart.^{991,992} Both forms are more common in adolescent males.⁹⁹³ No case of cutaneous involvement was recorded in a large series of cutaneous lymphomas in patients younger

Figure 41.26 Precursor T-lymphoblastic leukemia/lymphoma. Features shown here include single file infiltration between collagen bundles and medium-sized cells with high nuclear-to-cytoplasmic ratios and irregular nuclear contours. (H&E)

than 20 years of age.⁹⁹⁴ In a recent series of 13 cases presented by Lee *et al.*, 7 represented precursor T-lymphoblastic lymphoma.⁹⁹⁵ Lesions were found on the head and neck and the trunk. All cases represented secondary involvement, with involvement of lymph nodes, mediastinum, and/or bone marrow. Three patients underwent remission with chemotherapy and local radiation therapy, but three patients relapsed and two died with progressive disease.⁹⁹⁵

Histopathology

There are diffuse dermal infiltrates with sparing of the epidermis and a grenz zone between the infiltrate and the overlying epidermis. Single-file infiltration between collagen bundles is noted. The infiltrates involve the dermis and subcutis, and they consist of medium-sized cells with a high nuclear:cytoplasmic ratio, irregular nuclear contours, and sometimes prominent nucleoli (Fig. 41.26). A focal 'starry sky' arrangement is noted in some cases. Adnexal structures are mostly intact, but focal destruction of these structures can be observed.⁹⁹⁵ The cells have a CD3⁺, CD5⁺, CD4⁺, CD8⁺, CD10⁺, and TdT⁺ immunoprofile. Cells are also positive for CD99. There is monoclonal TCR gene rearrangement.^{992,993} EBV viral RNA is negative.⁹⁹⁵

Differential diagnosis

Some examples of precursor T-lymphoblastic leukemia/lymphoma have a 'starry sky' appearance that can mimic Burkitt's lymphoma or variants of mantle cell lymphoma, both of which are uncommon in skin. However, nuclear TdT positivity confirms the diagnosis of lymphoblastic lymphoma. In contrast to blastic plasmacytoid dendritic cell neoplasm, which can also show TdT positivity, the neoplastic cells of precursor T-lymphoblastic lymphoma (PTLL) lack the characteristic markers of plasmacytoid dendritic cells, such as CD123. Differential B-cell and T-cell staining can be used to determine the precise lineage of the neoplastic cells.

T-CELL PROLYMPHOCYTIC LEUKEMIA

This is a rare aggressive leukemia in which there are cutaneous manifestations in many cases at the time of diagnosis – 24% in one series.⁹⁹⁶ As well as a lymphocytosis, there is lymphadenopathy and splenomegaly. There is a propensity for skin manifestations to involve the

Figure 41.27 T-cell prolymphocytic leukemia. The infiltrate is composed of small to intermediate-sized lymphocytes with high nuclear-to-cytoplasmic ratio and irregularly shaped or oval nuclei with finely dispersed chromatin. Nucleoli are not readily identified in this example. (H&E)

face, often symmetrically, but the limbs and trunk may also be involved. There is often a diffuse infiltrated erythema. Edematous and purpuric lesions, plaques and nodules, and erythroderma may also be present.^{996,997}

Histopathology

There is a perivascular and periappendageal infiltrate involving the dermis, sometimes extending into the subcutis; the epidermis is spared.⁹⁹⁶ The infiltrating cells are small to intermediate-sized lymphocytes with oval, reniform, and irregular nuclei having finely dispersed chromatin and a small single central nucleolus. There is a high nuclear:cytoplasmic ratio. The nucleus may be eccentrically placed (Fig. 41.27).⁹⁹⁷

Immunohistochemistry and cytogenetics

In T-cell prolymphocytic leukemia, the cells are CD2⁺, CD3⁺, CD5⁺, and CD7⁺. Approximately two-thirds of cases are CD4⁺, but they may be CD4⁺/CD8⁺ or CD4⁺/CD8⁺.^{1,998} Cells also stain in a nuclear and cytoplasmic pattern for TCL1.⁹⁹⁸

There is clonal TCR gene rearrangement. Chromosome 14 inversion is characteristic.^{997,998}

ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA

Angioimmunoblastic T-cell lymphoma (AITL) was originally known as angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) and was considered an abnormal immune reaction with B-cell hyperplasia.⁹⁹⁹ It is now regarded as a T-cell lymphoma because most cases have clonal TCR gene rearrangements.¹⁰⁰⁰ The pathogenesis of AITL is uncertain. It has been proposed that the disease begins as a primary monoclonal proliferation of T cells or is initially a polyclonal response to a drug or virus that then evolves into a monoclonal proliferation.^{1001,1002} It is characterized by generalized lymphadenopathy; hepatosplenomegaly; constitutional symptoms such as fevers, night sweats, and weight loss; polyclonal hypergammaglobulinemia; and, in approximately 50% of cases, a skin rash.^{1003,1004} This often consists of a non-specific, generalized maculopapular rash resembling a viral exanthem or drug eruption. Lesions may precede or occur concurrently with systemic disease and are commonly on the trunk and limbs. Other

Figure 41.28 Angioimmunoblastic T-cell lymphoma. A number of atypical lymphocytes are seen in this example, including cells with features of immunoblasts. (H&E)

cutaneous manifestations include erythematous plaques, nodules, and urticarial and purpuric lesions. Lesions may regress spontaneously or after corticosteroid therapy. It occurs most commonly in the elderly. The median survival in this condition is 11–30 months.⁹⁹⁹ Infections are common complications. A second nodal EBV-associated B-cell lymphoma may develop.^{1,1005} Cutaneous B-cell lymphoma has also been reported in association with this condition.^{1006,1007}

Histopathology¹⁰⁰¹

The histological appearance of lesions is variable: the most common pattern is a nonspecific perivascular infiltrate of non-atypical lymphocytes with some vascular proliferation.¹⁰⁰¹ In some cases, there is a sparse perivascular infiltrate of pleomorphic lymphocytes.

In cases most recognizable as lymphoma, there is a variably dense perivascular and periappendageal infiltrate that may extend into the subcutis. Cellular infiltrates are polymorphous and include variable numbers of large atypical lymphocytes, medium and small lymphocytes and admixed histiocytes, plasma cells, and eosinophils (**Fig. 41.28**). Rarely, Reed–Sternberg-like cells are seen.¹⁰⁰⁵ Proliferation of postcapillary venules is also seen in many biopsies, similar to the vascular proliferation seen in lymph nodes. Occasionally, there is a leukocytoclastic vasculitis with extravasated red blood cells. An infiltrate with granulomas¹⁰⁰⁸ and one with necrotizing granulomas have been reported.¹⁰⁰⁹

The most characteristic histopathologic changes of AITCL are identified in lymph nodes. These consist of diffuse infiltrates of small to medium lymphocytes, many of which have the characteristics of immunoblasts, showing generous amounts of pale to clear cytoplasm and round to oval, vesicular nuclei with one or more eosinophilic nucleoli. Reed–Sternberg-like cells are sometimes identified.¹⁰¹⁰ To varying degrees, these lymphocytes produce effacement of the normal lobular architecture of the node, although hyperplastic germinal centers with ill-defined borders have been described in some cases.¹⁰¹¹ This process is associated with arborizing postcapillary venules¹⁰⁰² and interstitial deposits of eosinophilic material.

Immunohistochemistry and cytogenetics

The atypical neoplastic lymphocytes express T-cell antigens CD2, CD3, CD4, and CD45RO. Neoplastic T cells have been reported to show aberrant expression of CD10 in nodes and at extranodal sites.^{1012,1013} These cells also frequently express CXCL-13, a chemokine normally expressed by follicular helper T cells; it was demonstrated in 80% of skin biopsies in one series.¹⁰¹⁴ Other markers for follicular

helper T cells include SLAM-associated protein (SAP), PD-1, and c-Maf.¹⁰¹⁵ Overexpression of c-Maf (a member of the basic leucine zipper transcription factors belonging to the AP-1 superfamily) has been demonstrated in the neoplastic T cells in frozen sections.¹⁰¹⁶ It now appears to be available for use in paraffin-embedded tissues.

In lymph nodes, CD21⁺ dendritic cells surround the arborizing vessels, and there is also a network of desmin-positive cells that are characterized by long cytoplasmic processes.¹⁰¹⁷ The Reed–Sternberg-like cells are CD30⁺ and CD15⁺, and they sometimes express CD20.¹⁰¹⁰

There are also CD20⁺ B cells in the background population of cells. EBV is detected in lymph nodes in the majority of cases of AITL but only in a few isolated lymphocytes. It has been reported only rarely in skin lesions.^{1001,1005,1018} Clonal TCR gene rearrangements have been reported in 75% of lymph nodes and have also been reported in the skin, even in nonspecific infiltrates. DNA microarray analysis has been performed on a limited number of cases.¹⁰¹⁹

Differential diagnosis

Because the cutaneous changes in AITL often appear to be nonspecific and can resemble a variety of inflammatory dermatoses, diagnosis of this lymphoma requires a high index of suspicion and detailed knowledge of all the clinical features. Because more diagnostic changes are usually seen in affected lymph nodes, lymph node biopsy is essential. T-cell receptor gene rearrangements can be found even when clinical and histopathologic changes are nonspecific.¹⁰⁰¹ Among the changes in lymph nodes, perivascular proliferations of CD21⁺ follicular dendritic cells and networks of desmin-positive cells are considered highly characteristic of AITL.¹⁰¹⁷ The presence of Reed–Sternberg-like cells can lead to an erroneous diagnosis of Hodgkin's disease; therefore, all of the other morphologic features as well as T-cell clonality should be taken into account when formulating the diagnosis. An example of relapsed AITL following chemotherapy showed epidermotropism within cutaneous plaque-like lesions, mimicking MF. However, the infiltrating cells were found to express CD10 and the follicular helper T-cell markers PD-1, bcl-6, and CXCL-13.¹⁰²⁰

PRIMARY SYSTEMIC ANAPLASTIC LARGE CELL LYMPHOMA

The primary systemic form of ALCL can be further subdivided by whether or not the tumor cells express ALK. ALK⁺ and ALK[−] cases have different clinical presentations and response to therapy.¹⁰²¹

ALK⁺ systemic ALCL occurs most commonly in the first three decades of life with a definite male predominance (male:female ratio, 3:1). Extranodal involvement occurs in 60% of cases, with the skin being the most common extranodal site (21% of cases). ALK[−] systemic ALCL is more common in older age groups, and there is an almost equal sex incidence (male:female ratio, 0.9:1). ALK⁺ cases have a better response to therapy and prognosis than do ALK[−] cases.³⁷

Skin presentation may precede the detection of a systemic lymphoma.¹⁰²² An erythrodermic form has rarely been reported.¹⁰²² Primary systemic ALCL has been associated with acquired ichthyosis.¹⁰²³

Histopathology

The common type of cells in ALCL are large lymphoid cells with chromatin-poor, horseshoe-shaped, or embryo-shaped nuclei, multiple prominent eosinophilic nucleoli and abundant cytoplasm, often with a pale paranuclear hof. These cells are sometimes referred to as 'hallmark' cells and are seen in all cytological forms of ALCL. In most cases, the cells vary in size and shape, but they are sometimes relatively monomorphous.¹⁰²⁴ The common type of ALCL comprises 60–70% of all cases. Multinucleate cells resembling Reed–Sternberg cells may also be seen.^{225,1025} The small cell variant has a mixture of

small, medium, and large lymphoid cells. Large cells often surround vessels. Small cells are often CD30⁺.¹⁰²⁶ In the lymphohistiocytic variant, there is a heavy histiocytic infiltrate that may mask the smaller neoplastic cell population of lymphoid cells. Cells are often smaller than those in common ALCL.¹⁰²⁷ The small cell type and the lymphohistiocytic type represent approximately 5 and 15% of cases, respectively, and are predominantly in the pediatric group.^{1028,1029} The giant cell variant is characterized by many multinucleate cells.²²⁵ A sarcomatoid variant resembles a soft tissue sarcoma and contains large atypical, often spindle-shaped cells.¹⁰³⁰ Eosinophil-rich and neutrophil-rich variants have also been described.^{1031–1034} A rare signet-cell type has also been reported.¹⁰³⁵

In cutaneous involvement, there may be a diffuse dermal infiltrate or an infiltrate restricted to perivascular and periappendageal sites.¹⁰³⁶ The epidermis is spared.

Immunohistochemistry and cytogenetics

Tumor cells by definition are predominantly CD30⁺, with staining of the cell membrane and Golgi zone. ALK-1 is positive in 60% of cases. The majority are EMA⁺. CD45 is expressed in 60% of cases. T-cell antigens CD3, CD2, and CD45RO are seen in approximately 50% of cases. A minority are CD4⁺ or CD8⁺. CD56, TIA-1, granzyme B, and perforin may be expressed.^{225,1025,1037}

ALK protein is absent in normal tissues except the brain, and expression in other tissues indicates anomalous ALK expression usually in the form of nucleophosmin (*NPM-ALK*) fusion protein associated with a t(2;5)(p23;q35) translocation. Other translocations, such as t(1;2)(q21;p23), t(2;3)(p23;q21), and inversion² (p23;q35), have also been reported. Immunohistochemistry, FISH, and ALK gene rearrangement studies are equally effective in identifying ALK⁺ cases.

As stated previously, the skin lesions in primary cutaneous ALCL are almost invariably ALK⁺ and do not have the t(2;5) translocation, although rare ALK⁺ cases with or without the t(2;5) translocation have been reported.^{544,1038–1041} CD44 (a cell surface adhesion molecule) is highly expressed in both systemic and cutaneous forms of ALCL, whereas the variant form CD44v6 is expressed in 90% of the systemic form but in only 50% of the cutaneous form.⁵⁷⁸

Approximately 90% of systemic ALCL exhibit clonal TCR gene rearrangements whether or not they express T-cell antigens. The remainder show no rearrangements of TCR or Ig genes.¹⁰⁴²

EBV is not expressed in cells.¹⁰⁴³

INTRAVASCULAR T- AND NK-CELL LYMPHOMA

Cases of intravascular lymphoma of T-cell or NK-cell type are very rare.^{724,921,1044–1046} In one series of intravascular lymphoma, they represented 2.6% of cases.⁸⁸⁵ Clinical presentation is similar to those with the B-cell form, with the skin being the predominant presenting site, followed by the central nervous system. The trunk and extremities are predominantly involved.⁹²¹ Unlike the B-cell form, there is a common association with EBV. The prognosis is very poor and worse than that of the conventional lymphoma of that type.¹⁰⁴⁴

Histopathology

Vessels in the dermis and subcutis contain intermediate to large atypical lymphocytes. Sometimes the vessels are surrounded by smaller, non-neoplastic lymphoid cells.^{921,1045} Thrombi may be present in vessels.⁷²⁴ Apoptotic bodies may also be identified in vessel lumina.

Immunohistochemistry and cytogenetics

The phenotype is variable and can be of a NK- or T-cell type. NK-cell tumors may have a phenotype similar to the NK/T-cell lymphoma, nasal type. T-cell tumors may express cytotoxic markers.¹⁰⁴⁶ T-cell tumors have clonal rearrangement of TCR genes; in NK lymphoma,

TCRs are germline. Cases may have an anaplastic large cell phenotype (CD30⁺).¹⁰⁴⁷ EBV is present in more than half the cases reported.⁹²¹

AGGRESSIVE NK-CELL LEUKEMIA

Aggressive NK-cell leukemia, also known as aggressive NK-cell leukemia/lymphoma,¹⁰⁴⁸ is a very rare disorder in Western countries, with most reports coming from Japan.^{716,1049,1050} It occurs in a younger age group than does NK/T-cell lymphoma, nasal type (median age, 30 years) in reported cases,¹⁰⁴⁹ but there is overlap between these two conditions. It is characterized by an aggressive disease with fevers and hepatosplenomegaly as well as lymph node and bone marrow involvement. There are circulating atypical large lymphoid cells with azurophilic granules. Skin involvement is said to be rare,¹⁰⁵¹ but in one review of the literature it was present in almost 50% of cases.¹⁰⁴⁹

Histopathology

Features overlap with those of extranodal NK/T-cell lymphoma, nasal type. There is a dermal infiltrate of mononuclear cells that are arranged in an angiocentric pattern with angioinvasion and destruction.¹⁰⁵²

Immunohistochemistry

The cells are CD2⁺, surface CD3[−] (cytoplasmic CD3e⁺), CD56⁺, CD4[−], and CD8[−]. TCR receptors are germline. Cells are positive for EBV ISH.^{710,716,1049}

OTHER T/NK-CELL LYMPHOMAS AND LEUKEMIAS

T- and NK-large granular cell leukemias very rarely present as specific infiltrates in the skin.¹⁰⁵³ Other nonspecific skin manifestations are much more common.^{1054,1055} There are circulating lymphocytes with abundant cytoplasm and coarse azurophilic granules. The majority are of T-cell type (80%).¹⁰⁵³ The common immunophenotype of the T-cell form is CD3⁺, CD4[−], CD8⁺ with variable CD56 and TIA-1. There are clonal TCR gene rearrangements. The NK variant is CD3[−] with no TCR gene rearrangements. There is an indolent course in most cases.

Cutaneous lesions of Lennert's lymphoma (lymphoepithelioid T-cell lymphoma) have rarely been reported.¹⁰⁵⁶

An indolent CD8⁺ T-cell lymphoma occurring on the ear has been reported.⁶⁷⁸ In these cases, there is a dermal infiltrate of monomorphic medium-sized cells with an irregular nucleus, small nucleoli, and minimal cytoplasm. There is no epidermotropism. The cells have a CD3⁺, CD8⁺, TIA-1, CD45RA, β -F1 immunoprofile.

There remains a group of peripheral T-cell lymphomas, unspecified that present in the skin. They have been divided into small/medium-sized T-cell lymphomas and CD30[−] large T-cell lymphomas. Apart from a small group of CD3⁺, CD4⁺, CD8[−] small/medium-sized T-cell lymphomas with solitary or localized skin lesions (discussed previously), this group of lymphomas has an unfavorable prognosis, with an overall 5-year survival of 20%.⁷⁷¹

OTHER B-CELL LYMPHOMAS THAT MAY INVOLVE THE SKIN

PRECURSOR B-LYMPHOBLASTIC LEUKEMIA/LYMPHOMA

A small number of patients present primarily as a lymphoma (PBL) rather than a leukemia (PBLA). Unlike PTLL, which commonly involves lymph nodes and mediastinum, PBL usually involves extranodal sites, with the skin being the most common site of extranodal presentation. Cutaneous presentation of PBL occurs in children,

Figure 41.29 Precursor B-lymphoblastic leukemia/lymphoma. This monotonous infiltrate is composed of medium-sized lymphoid cells with rounded to convoluted nuclei. Nucleoli are inconspicuous, and there is scant cytoplasm. (H&E)

including the very young,¹⁰⁵² and adults,^{992,1057,1058} with the head and neck region being the most commonly involved sites. The lesions are erythematous or violaceous papules or nodules. PBLA may present with urticarial skin lesions.¹⁰⁵⁹ Although systemic spread is demonstrated when staging is undertaken, there are reported cases limited to the skin.¹⁰⁶⁰ Aggressive chemotherapy may prevent progression to leukemia,¹⁰⁶⁰ and PBLL appears to have a better prognosis than PBLA.

Histopathology^{991,1060}

The neoplastic infiltrate involves the dermis and subcutis with sparing of the epidermis. There is commonly a 'starry sky' pattern with gaps in the infiltrate containing macrophages with cell debris. A vague nodular pattern can be produced by collagen compartmentalization. Crush artifact and the 'Azzopardi effect' (basophilic smearing of collagen fibers) are common in biopsies. The cellular infiltrate is monomorphic and consists of medium-sized lymphoid cells with round or convoluted nuclei, inconspicuous nucleoli, and little cytoplasm. Numerous mitotic figures can be present, including atypical forms (Fig. 41.29).

Immunohistochemistry and cytogenetics

The neoplastic cells express the B-cell marker CD79a and, less commonly, CD20. They are CD10⁺, TdT⁺, CD99⁺, and bcl-2⁺ in most cases, but not always.¹⁰⁵² CD99 is particularly useful in distinguishing this lymphoma from other B-cell lymphomas. Cells are Pax5⁺, whereas the cells in T-lymphoblastic leukemia/lymphoma are negative.⁸⁸³ The cytogenetics of this condition are complex and are prognostically important. Rearrangement of the *MLL* gene and hyperdiploidy have been reported in cutaneous lesions.¹⁰⁵⁸

Differential diagnosis

The differential diagnosis includes Burkitt's lymphoma and blastoid mantle cell lymphoma, both of which can display a 'starry sky' microscopic image. However, both of these neoplasms are uncommon in skin, and among the three lesions, lymphoblastic lymphoma is the only one that shows nuclear TdT positivity.

CHRONIC LYMPHOCYTIC LEUKEMIA/SMALL LYMPHOCYTIC LYMPHOMA (B-CLL)

The specific infiltrates of B-CLL include localized or generalized, erythematous papules, plaques, nodules, and large tumors. Unusual pres-

entations include involvement of parts of the face and ears.¹⁰⁶¹ Reflecting the fact that B-CLL occurs predominantly in older adults,¹ the mean age of presentation in one series was 66 years.¹⁰⁶² Uncommonly, skin lesions may represent the first sign of the disease.¹⁰⁶²⁻¹⁰⁶⁴ Lesions may present in the scars of herpes zoster or varicella, or herpes simplex lesions.¹⁰⁶⁵⁻¹⁰⁶⁷ It may also occur at sites typical for lymphoid hyperplasia associated with *B. burgdorferi* infection, such as the nipple and scrotum.¹⁰⁶⁸ Occasionally, B-CLL and MF occur together.¹⁰⁶⁹ Acute myelogenous leukemia cutis has also been described in association with B-CLL.¹⁰⁷⁰

The 5-year survival of B-CLL with cutaneous lesions is 66%. Transformation to large B-cell lymphoma (Richter's syndrome) is associated with a poor prognosis.

Histopathology

Patterns of dermal infiltration include perivascular and periappendageal, nodular, diffuse, and band-like.¹⁰⁶² The cellular infiltrate consists of a monomorphous population of small lymphocytes. Proliferation centers, which are pale areas containing larger prolymphocytes and paraimmunoblasts, are uncommon.¹⁰⁶² Varying numbers of larger cells resembling centroblasts and immunoblasts are present in cases undergoing transformation to a large B-cell lymphoma. There may be epidermal changes of acanthosis and ulceration. Other reactive cells including eosinophils, neutrophils, histiocytes, and plasma cells may be present.¹⁰⁷¹

The leukemic infiltrate may surround epithelial neoplasms such as basal cell carcinoma and squamous cell carcinoma (Fig. 41.30).^{1072,1073} The pathologist should be alerted to this possibility when there is a dense basophilic dermal infiltrate evident with the naked eye in a slide of an excised skin lesion, particularly if it is present in a number of lesions that have been excised.

Immunohistochemistry and cytogenetics

The small lymphocytes are CD20⁺, CD5⁺, CD43⁺, and CD10⁻.^{1,1062} PCR demonstrates clonal IgH gene rearrangements.

MANTLE CELL LYMPHOMA

The majority of cases classified as mantle cell lymphoma (MCL) in the skin are secondary to nodal disease.¹⁰⁷⁴ Secondary skin involvement has been reported in up to 17% of cases of advanced disease.¹⁰⁷⁵ Cutaneous lesions may be the first manifestation of the disease.⁶⁸²

Histopathology

As defined in the WHO classification, this is a lymphoma composed of small to medium-sized lymphocytes with irregular or cleaved nuclei with dispersed chromatin, inconspicuous nucleoli, and scant cytoplasm most closely resembling centrocytes/cleaved follicular center cells.¹⁰⁷⁶ A 'blastoid' variant with cells resembling lymphoblasts with larger nuclei and dispersed chromatin has also been described with skin involvement.¹⁰⁷⁷

In two possible cases of primary MCL, there were nodular infiltrates of the characteristic cells surrounding atrophic germinal centers in a mantle zone pattern (Fig. 41.31); the dermis and subcutis were involved with sparing of the epidermis.¹⁰⁷⁸ Plasma cells were present at the periphery of the nodules.

Secondary involvement most often takes the form of a perivascular or periappendageal infiltrate or a diffuse infiltrate that spares the epidermis but may extend into subcutis. The infiltrate is reported to have the blastoid subtype frequently.¹⁰⁷⁹

Figure 41.30 Basal cell carcinoma associated with an infiltrate of B-cell chronic lymphocytic leukemia. (H&E)

Immunohistochemistry

The neoplastic cells are CD20⁺, CD5⁺, CD43⁺, CD10⁻, CD23⁻, and bcl-6⁻. Some cases are CD5⁻. Rare cases have aberrant bcl-6 expression. Most have nuclear staining for cyclin D1 (**Fig. 41.32**).⁸²⁰ The expression of this nuclear protein is due to overexpression of the *PRAD1* gene as a result of the translocation t(11;14)(q13;q32) involving the immunoglobulin heavy-chain locus and the bcl-1 locus. The translocation is characteristic of MCL^{820,1080} and can be demonstrated by FISH, PCR, or conventional cytogenetics.^{1079,1081}

PRIMARY EFFUSION LYMPHOMA

Primary effusion lymphoma is a rare lymphoma of large B cells that presents as serous effusions without an associated tumor mass. In most cases, but not all, it is associated with HHV-8 infection. It is most commonly seen in young patients with HIV/AIDS¹⁰⁸² but can also be seen in transplant recipients and elderly men in areas with a high prevalence of HHV-8. It has rarely been reported secondarily in the skin.¹⁰⁸³ In a reported case, there was a diffuse infiltrate of large B cells (CD20⁺, CD79a⁺, CD3⁻) in the dermis and subcutis.¹⁰⁸³

Figure 41.31 Mantle cell lymphoma. In this rare example of cutaneous involvement with mantle cell lymphoma, there are nodular infiltrates of atypical cells. Several atrophic germinal centers are surrounded by these cells. (H&E)

Figure 41.32 Mantle cell lymphoma. Many of the cells display nuclear staining for cyclin D1. (Immunohistochemistry for cyclin D1)

LYMPHOPLASMATIC LYMPHOMA/ WALDENSTRÖM'S MACROGLOBULINEMIA (LL/M)

The current WHO classification defines this rare entity as a lymphoma of small B lymphocytes, plasma cells, and plasmacytoid cells associated with an IgM paraprotein.¹⁰⁸⁴ The immunoprofile of the component cells is usually CD5⁻, CD10⁻, and CD23⁻.^{1084,1085} There appears to be some overlap with marginal zone B-cell lymphoma.¹⁰⁸⁵ The term 'immunocytoma' is confusing and has been used for LL/M as well as marginal zone lymphoma in the skin. Cases with cutaneous presentation have been described.¹⁰⁸⁶

γ Heavy-chain disease is classified as a variant of LL/M in the current WHO classification.¹⁰⁸⁷ It is a biochemical expression of a mutant clone of B cells that produces abnormal, incomplete γ heavy chains, devoid of light chains.¹⁰⁸⁸ It is usually associated with a

lymphoplasmacytic proliferative disorder, although the associated clinical and histological findings are varied.¹⁰⁸⁹ Cutaneous involvement is rare, being present in less than 5% of the reported cases.¹⁰⁸⁸ The usual skin lesions are erythematous infiltrated plaques and nodules on the trunk and extremities. Livedo reticularis and digital necrosis caused by associated necrotizing arteritis have been reported.¹⁰⁹⁰

Histopathology

In the few reported cases of γ heavy-chain disease with cutaneous involvement, there has been a dermal infiltrate of lymphoplasmacytic cells, immunoblasts, and mature plasma cells.¹⁰⁸⁸ In one case, vascular proliferation and the presence of eosinophils led to an initial diagnosis of angiolymphoid hyperplasia with eosinophilia.^{1089,1091} Sometimes the cells have a conspicuous periadnexal distribution.

BURKITT'S AND BURKITT-LIKE LYMPHOMA

This lymphoma has rarely been reported in the skin as a secondary lesion.¹⁰⁹² It may present in the skin around nodal biopsy sites,¹⁰⁹³ and it has been reported in a background of HIV/AIDS.^{771,1094} In Burkitt's lymphoma (BL), there is an infiltrate of monomorphous medium-sized cells with round nuclei and multiple central nucleoli. There are numerous mitotic figures, and macrophages with phagocytosed apoptotic bodies are frequent, producing the characteristic 'starry sky' appearance (Fig. 41.33). In Burkitt-like lymphoma (BL-L), the cells are slightly larger and more pleomorphic; there are overlapping features with diffuse large B-cell lymphoma. Both BL and BL-L have a proliferation fraction approaching 100% (with Ki-67). The cells are CD20⁺, CD10⁺, CD43⁺, and bcl-6⁺. BL is characterized by a translocation of the MYC proto-oncogene on chromosome 8 (t(8;14) or t(2;8)).

PLASMACYTOMA AND SECONDARY MYELOMA

Although plasmacytomas are now regarded as variants of lymphoma, they were considered in Chapter 40, page 1136, with other diseases of plasma cells.

Figure 41.33 Burkitt's lymphoma. There are monomorphous medium-sized cells with multiple nucleoli. Scattered macrophages with phagocytosed apoptotic bodies are seen, creating the 'starry sky' appearance. Although typical of Burkitt's lymphoma, a 'starry sky' pattern can sometimes be observed in precursor T-lymphoblastic lymphoma or mantle cell lymphoma. (H&E)

OTHER LYMPHOMAS

HODGKIN'S LYMPHOMA

Infiltration of the skin is usually a late manifestation of Hodgkin's lymphoma (HL) and develops in 0.5–3.4% of patients according to old literature.^{1095–1097} Current experience suggests it has decreased in incidence because of improved therapy for nodal disease.¹⁰⁹⁸ Lesions often occur in a localized area of the trunk or on the proximal part of the extremities in the vicinity of involved lymph nodes, suggesting retrograde lymphatic spread.^{1095,1099} Hematogenous and in-continuity direct spread are other potential routes of dissemination. Direct skin invasion from nodes may mimic scrofuloderma.¹¹⁰⁰

Cutaneous lesions may be papules, nodules, or plaques, although rare clinical presentations have included multiple ulcers on the scalp,¹¹⁰¹ a bullous eruption,¹¹⁰² and widespread lesions. Paradoxically, two of the cases with widespread deposits had a more prolonged survival than is usually seen with cutaneous disease.¹¹⁰³ Spontaneous regression of the skin lesions has been reported.¹¹⁰⁴

Skin lesions may rarely be the initial manifestation of HL, with lymph node involvement appearing some months or years later.^{1105–1110} Primary cutaneous HL is a controversial entity, although rare cases appear to exist.^{675,1111} Some cases previously reported may represent lymphomatoid papulosis or anaplastic large cell lymphoma. Cases of lymphomatoid papulosis followed by HL have been reported.^{627,628} Primary cutaneous HL may pursue a benign course, although up to 50% of patients develop nodal or systemic disease.^{675,1111}

A variety of nonspecific skin manifestations are commonly found in the skin in HL, including pruritus, herpes zoster, and acquired ichthyosis. Less common associations have included urticaria, eczema, erythema multiforme, erythema nodosum, drug eruptions, bullous pemphigoid, dermatitis herpetiformis, pemphigus, acquired epidermolysis bullosa, follicular mucinosis, alopecia, lymphedema, dermatomyositis, and granuloma annulare.¹¹¹² Numerous examples of concurrent HL and MF have been reported. Rarely, MF and cutaneous HL have been reported together.^{1109,1113}

The WHO classification divides HL into classic HL (including nodular sclerosis, lymphocyte-rich classic, mixed cellularity, and lymphocyte depletion subtypes) and nodular lymphocyte predominance HL, which is now regarded as a separate clinicopathological entity.¹

The neoplastic cells of HL have been shown to be clonally derived from germinal center B cells that have lost the capacity to produce or express immunoglobulin.^{1114,1115} In addition, many epidemiological and molecular studies suggest that EBV plays a significant etiological role in HL.^{1116–1118} *In situ* hybridization studies for EBV have demonstrated abundant viral transcripts in Reed–Sternberg cells.¹¹¹¹

Histopathology

There is a diffuse infiltrate of cells involving the dermis and subcutis. A grenz zone is usually present. Skin appendages and blood vessels are frequently invaded.¹¹⁰⁶ There is a mixed cellular infiltrate that includes mononuclear variants of Reed–Sternberg cells and variable numbers of classic Reed–Sternberg cells in a background of small lymphocytes, eosinophils, and sometimes neutrophils (Fig. 41.34). Fibrosis is another common feature. The histology may resemble that of nodular sclerosis or mixed cellularity types; lymphocyte depletion may be present in advanced stages.¹⁰⁹⁵ Nonspecific changes reported in the skin in association with the lymphomatous infiltrate include epithelioid granulomas¹¹¹⁹ and palisading necrobiotic granulomas.¹¹²⁰

The histology of HL, lymphomatoid papulosis, and anaplastic large cell lymphoma has many features in common. Neutrophils and eosinophils have been reported in lesions from all these conditions and are

Figure 41.34 Cutaneous Hodgkin's lymphoma. Numerous Reed–Sternberg cells are present. (H&E) The cells are CD15⁺ (top inset) and CD30⁺ (lower inset). (Immunoperoxidase stains for CD15 and CD30)

not a discriminating feature. Occasionally, Reed–Sternberg-like cells may be seen in lymphomatoid papulosis and anaplastic large cell lymphoma.

Immunohistochemistry and cytogenetics

Reed–Sternberg cells and mononuclear variants are CD30⁺, CD15⁺ in most cases and are CD45[−], CD45RO[−], CD43[−], and EMA[−]. Occasional cases are CD15[−].¹⁰⁹⁶ Cells may occasionally express B-cell markers CD20, Oct-2, and BOB.1 but in a patchy manner.¹¹²¹ They are usually Pax5⁺, whereas the cells of anaplastic large cell lymphoma do not stain.⁸⁸³ EBV may be demonstrated in cells by immunohistochemistry for LMP-1 or by *in situ* hybridization for EBER.¹¹²² The background population of small lymphocytes is predominantly CD3⁺, CD4⁺ T cells.

Large cells in anaplastic large cell lymphoma and lymphomatoid papulosis are usually CD30⁺, CD15[−], and CD45 may be negative in some cases.³⁷ They may be EMA⁺ more commonly in the primary systemic form than in the cutaneous form and lymphomatoid papulosis. ALK-1 may be positive in the systemic form, rarely in the cutaneous form, and never in HL.²²⁵

No cytogenetic studies have been performed on cutaneous disease. Studies on HL in lymph nodes have shown clonal rearrangements of immunoglobulin genes in tissue occasionally but in 98% of isolated Reed–Sternberg cells.¹¹²¹

Differential diagnosis

Cutaneous lesions with heavy mixed infiltrates could be confused with a variety of inflammatory dermatoses, unless the typical cells of Hodgkin's disease are identified; this is less of a diagnostic problem when there is a known history of nodal or systemic disease. The neoplastic cells of Hodgkin's disease closely resemble the atypical cells of type A lymphomatoid papulosis. Lymphomatoid papulosis can precede the onset of Hodgkin's disease, and rare cases of primary cutaneous Hodgkin's disease present with self-healing papulonodular lesions that are close clinical mimics of lymphomatoid papulosis. Although the atypical cells of lymphomatoid papulosis are also CD30⁺, they are usually CD15[−] and CD45⁺, in contrast to Hodgkin and Reed–Sternberg cells. CD30⁺ ALCL can also resemble Hodgkin's disease. However, the polymorphous inflammatory infiltrates of some forms of Hodgkin's disease can be distinctive.⁶⁷⁵ Furthermore, in contrast to ALCL, the

neoplastic cells of Hodgkin's disease are positive for B-cell-specific activator protein and are negative for epithelial membrane antigen and the ALK protein; the latter two staining results help to make a distinction from systemic ALCL.^{1121,1123} Although the neoplastic cells in primary cutaneous CD30⁺ large cell lymphoma are also typically negative for epithelial membrane antigen and ALK, those cells are usually positive for CD4.³ Positivity for EBV latent membrane protein also favors Hodgkin's disease in this context.³ A distinction from anaplastic large B-cell lymphoma may not always be possible, but this is not likely to be a major issue in cases of cutaneous Hodgkin's disease, particularly when all the clinical and histopathologic features are taken into account. Cho and colleagues reported an example of cutaneous nodules occurring in a man with classic Hodgkin's lymphoma. As in a lymph node biopsy, the cutaneous Reed–Sternberg and Hodgkin cells showed weak PAX5 positivity and weak focal Oct-2 positivity and were negative for BOB.1. These results are consistent with Hodgkin's lymphoma and argue against T-cell lymphoma (in which all three markers are absent) and other non-Hodgkin B-cell lymphomas (in which all three markers are strongly expressed).^{1124–1126}

CUTANEOUS INFILTRATES OF LEUKEMIAS

Some of the leukemias have already been discussed with their lymphomatous counterparts. A discussion of myeloid leukemia and its subtypes follows.

MYELOID LEUKEMIAS, MYELOPROLIFERATIVE DISEASES, AND MYELODYSPLASTIC SYNDROMES

Cutaneous infiltrates have been described in many forms of acute myeloid leukemia, chronic myeloproliferative diseases (e.g., chronic myeloid (myelogenous) leukemia), and in the setting of myelodysplastic syndromes and myeloproliferative syndromes as a sign of transformation to an acute leukemia.^{1127–1138}

Leukemia cutis, myeloid sarcoma, granulocytic sarcoma, and chloroma are all terms that have been used for leukemic infiltrates in extramedullary sites including the skin.¹¹³⁹ 'Chloroma' refers to tumor masses that are green in color on exposure to light due to the presence of myeloperoxidase.¹¹⁴⁰

Myeloid leukemic infiltrates can take many forms clinically but mostly present in adults as single¹¹⁴¹ or multiple macules, papules, nodules, or plaques, often with a red/brown or violaceous color in no particular distribution.¹¹³³ Unusual presentations include a stasis dermatitis-like eruption,^{1142,1143} a chilblain-like eruption,^{1144,1145} cutaneous hyperpigmentation,¹¹⁴⁶ and macrocheilia.¹¹⁴⁷ Leukemic infiltrates can occur in children and are sometimes congenital,^{1148,1149} or they precede demonstrable blood leukemia (aleukemic).¹¹⁵⁰ Spontaneous regression in a congenital case has been reported.¹¹⁵¹

Oral lesions, gum hypertrophy, and macroglossia have also been reported and are common in some subtypes, particularly acute monocytic and myelomonocytic forms.^{1133,1152} Lesions may precede the development of frank leukemia, often by months,^{1153–1157} and rare cases with long survivals (usually after chemotherapy) without progression to leukemia have been reported.^{1158–1160} Generally, the prognosis is poor, however.^{1129,1161} It may be the first sign of relapse after bone marrow transplantation for acute myeloid leukemia.¹¹⁶²

Commonly used classifications of this group of conditions include the French–American–British (FAB) classification¹¹⁶³ and the WHO classification.¹¹⁶⁴ The incidence of cutaneous involvement in acute myeloid leukemia is in the range of 2–20%,¹¹³⁵ and in chronic myeloid leukemia it is 0–4%.¹¹⁶⁵ Of acute myeloid leukemia, cutaneous involvement is most common in FAB type M4 (acute myelomonocytic

Figure 41.35 Cutaneous infiltration by myeloid blasts in a patient with acute myeloid leukemia. (H&E)

leukemia) and FAB type M5 (acute monocytic leukemia), but it is seen in most subtypes.^{1133,1135,1166} Skin infiltration is uncommon in chronic myelomonocytic leukemia.^{1167,1168} Rare leukemias such as myeloid/NK-cell precursor leukemia may present in the skin.¹¹⁶⁹

Histopathology¹¹³³

Leukemic infiltrates may take the form of perivascular and periappendageal infiltrates or confluent sheets of cells that involve the dermis and often the subcutis. There may be destruction of appendages. Sometimes there is percolation between collagen bundles in an 'Indian file' pattern reminiscent of the pattern seen in lobular carcinoma of the breast (Fig. 41.35). There may also be concentric layering of cells around vessels and adnexal structures.

The cell types present depend on the subtype of myeloid leukemia. In FAB M1 and M2 types (acute myeloblastic leukemia), the cells are predominantly atypical myeloblasts and myelocytes (medium to large mononuclear cells with a slightly eccentric basophilic nucleus, a single nucleolus, and a small amount of cytoplasm). FAB M4 and M5 types (acute myelomonocytic and monocytic leukemias) have infiltrates composed of medium-sized atypical round to oval monocytoïd cells with indented or kidney-shaped nuclei.

In chronic myeloid leukemia, the infiltrate is more pleomorphic with immature and mature granulocytes (myelocytes, metamyelocytes, eosinophilic metamyelocytes, and segmented neutrophils).¹¹³³ Metamyelocytes with large eosinophilic granules (eosinophilic metamyelocytes) are a useful clue that an infiltrate is of myeloid lineage and not lymphoma (Fig. 41.36).

Mitotic figures and apoptotic bodies are often seen. Other uncommon histological features include the presence of Langhans type giant cells¹¹⁷⁰ and leukemic vasculitis with leukemic cells in the walls of vessels sometimes with fibrinoid necrosis.^{1171,1172}

A positive naphthol AS-D chloroacetate esterase (NSAD) reaction was present in 64% of infiltrates in acute myeloid leukemia and 72% in chronic myeloid leukemia in one series.¹¹³³

Leukemic infiltrates have been reported in basal cell carcinoma,¹¹⁷³ psoriasis,¹¹⁷⁴ and Sweet's syndrome.¹¹⁶⁵

Immunohistochemistry and cytogenetics

The immunoprofile is determined by the type of myeloid infiltrate. Overall, CD68 and lysozyme are the most sensitive immunostains for the detection of myeloid leukemic infiltrates, but they are not lineage specific.¹¹³⁵

Figure 41.36 Acute myeloid leukemia. There is a heavy infiltrate of blasts, some of which contain conspicuous eosinophilic granules (top inset). Some cells are positive for myeloperoxidase (bottom inset). (H&E and immunoperoxidase stain)

Myeloperoxidase, CD45, CD74, HLA-DR, CD43, and Mac387 are expressed in a large percentage of cases. Myeloperoxidase is less useful in cases with monocytic differentiation. Other markers that may be present in a smaller percentage of cases include CD56, CD34, CD117, and CD15.^{1133-1135,1156} CD30 is expressed rarely.¹¹⁷⁵ A recently reported case of acute myeloid leukemia involving the skin was found to be CD56⁺ and myeloperoxidase negative.¹¹⁷⁶

Differential diagnosis

The presence of atypical cutaneous infiltrates with the morphologic changes described previously should suggest the possibility of leukemia cutis. A more detailed clinical and laboratory investigation should then follow; specific diagnosis depends on findings in bone marrow and peripheral blood. In the case of aleukemia cutis, close clinical follow-up is indicated to detect early development of systemic disease. A distinction from cutaneous lymphoma can be a major challenge, but it should be recognized that a number of these disorders (e.g., ATLL and acute lymphoblastic leukemia/precursor B-lymphoblastic lymphoma) have both leukemic and nonleukemic phases. Diagnosis may also be challenging when there are only a few atypical cells obscured by a dense, reactive infiltrate, as has been described in some lesions resembling Sweet's syndrome or pyoderma gangrenosum.¹¹⁷⁷ Regarding immunohistochemical staining, myeloid leukemia cutis is a likely diagnosis when CD3⁺/CD20⁻ infiltrates are found to be CD43⁺/MPO⁺ or CD43⁺, MPO⁻, CD68⁺, CD56⁻, CD117⁻.¹¹⁷⁸ Examples that are CD56⁺ can be distinguished from blastic plasmacytoid dendritic cell neoplasm by using stains for CD4 and CD123, which are positive in the latter disorder (CD4 may also be positive in myeloid leukemias with monocytic differentiation); those that prove to be CD117⁺ can be distinguished from mast cell sarcoma by staining for tryptase or microphthalmia transcription factor, each of which stains mast cells but not myeloid cells.^{1178,1179} S100 positivity has been reported in rare examples of myeloid leukemia cutis, and in one recent case, this was associated with cytophagic activity.¹¹⁸⁰ Such a result could lead to an erroneous diagnosis of melanoma, Rosai-Dorfman disease, or phagocytic activity associated with a lymphoid neoplasm, thus underscoring the need for use of immunohistochemical panels in addition to clinicopathologic correlation.

LYMPHOID HYPERPLASIAS MIMICKING PRIMARY LYMPHOMA

This category includes a variety of benign lymphoid proliferations that simulate cutaneous lymphoma clinically, but particularly histopathologically. The term 'pseudolymphoma' has been used for some of these conditions but is best avoided because it suggests a diagnostic category and several conditions included under this umbrella do not pose difficulties in their distinction from true lymphoma. Lymphomatoid papulosis was regarded in the past as a pseudomalignancy but is now classified with other cutaneous lymphomas (discussed previously).¹⁵

Traditionally, this group of conditions has been divided into B-cell and T-cell types based on the pattern and composition of the cellular infiltrate.¹¹⁸¹ The histological pattern may take the form of a superficial band-like infiltrate in the upper dermis (the so-called 'T-cell pattern') or a nodular or diffuse infiltrate in the dermis and sometimes subcutis (the so-called 'B-cell pattern'). This is an artificial distinction because predominantly T-cell proliferations may have a nodular pattern of dermal infiltration. In cutaneous lymphoid hyperplasia of the B-cell pattern, T cells are in fact more common than B cells.¹¹⁸²

Apparent clonal rearrangement of TCR genes or IgH genes by PCR must be interpreted with caution and correlated with the histological appearance. The problem of so-called 'pseudoclones' (a clone that on double or triple testing appears in a different position) has been addressed. The importance of duplicate or triplicate tests for clonality by PCR has been stressed to exclude overdiagnosis of clonality.¹¹⁸³

CUTANEOUS LYMPHOID HYPERPLASIA SIMULATING B-CELL LYMPHOMA

A plethora of terms have been used for this form of lymphoid hyperplasia: B-cell pseudolymphoma, B-cell cutaneous lymphoid hyperplasia, lymphadenosis benigna cutis, lymphocytoma cutis, and cutaneous lymphoplasia.^{1184,1185} These lesions usually present as asymptomatic red-brown or violaceous papules or nodules varying in diameter from 3 mm to 5 cm or more.¹¹⁸⁶ They may be solitary, grouped, or numerous and widespread.¹¹⁸⁷

The most common sites of involvement include the face (cheeks, nose, and earlobe), chest, and upper extremities.⁶³⁸ A xanthelasma-like presentation has been reported.¹¹⁸⁸ Females are affected more often than males. Lesions may resolve spontaneously after months or years, but there is a tendency for some to recur.^{1186,1187,1189} None of the clinical features allows reliable distinction from cutaneous lymphoma.

In most cases, the cause is unknown. Various stimuli are reported to induce this form of lymphoid hyperplasia,¹¹⁹⁰ including tick and other arthropod bites and stings;^{1191,1192} *Hirudo medicinalis* (leeches);¹¹⁹³ gold earrings and gold injections;^{1194,1195} cobalt;¹¹⁹⁶ zinc; tattoos (particularly the red-inked areas);¹¹⁹⁷⁻¹¹⁹⁹ a chronic draining sinus;¹²⁰⁰ ingestion of drugs such as phenytoin sodium,¹²⁰¹ methotrexate,¹²⁰² doxepin, and clozapine;¹²⁰³ hair coloring products (paraphenylenediamine);¹²⁰⁴ immunization;^{1205,1206} and specific immune therapy.¹²⁰⁷ Multiple cutaneous lesions have developed following allergen injections given for hyposensitization.^{1208,1209}

In Europe, cutaneous lymphoid hyperplasia (lymphocytoma cutis) has been associated with *Borrelia* infection and is said to be the most common cause in endemic areas.¹²¹⁰⁻¹²¹² This is a rare event in North American Lyme disease.¹²¹³ In this setting, lesions occur particularly on the earlobes, areolae of the nipples,¹²¹⁴ and scrotum – 89% of cases in one series.¹²¹² It has been described in association with acrodermatitis chronica atrophicans. The prevalence of *Borrelia*-associated cutaneous lymphoid hyperplasia has been reported to be from 0.6 to 1.3% of

cases in which there has been a clinical and/or serological diagnosis.¹²¹⁵ It is more common in women than in men, and it is seen in a wide age range that includes children.^{1212,1213}

The use of immunohistochemistry and molecular techniques, and a better understanding of the histopathological subtypes of cutaneous lymphoma, has made the distinction of cutaneous hyperplasia from low-grade cutaneous B-cell lymphomas more reproducible. The significance of a clonal proliferation of B cells in a histologically equivocal lesion remains controversial. The presence of a clonal B-cell population did not correlate with the subsequent behavior of lesions in one series. Occasionally, both B- and T-cell clonality has been demonstrated in the same case.^{1214,1216,1217} A monoclonal population of B cells was identified in 14% of cases diagnosed as pseudolymphoma on histological and clinical grounds in one study.¹²¹⁸ Another study proposed that there is a spectrum of cutaneous lymphoid proliferations that includes some lesions in which occult dominant clones can be identified by PCR or Southern blot analysis, with PCR being a more sensitive method of detection. In this study, dominant clones of B or T cells were demonstrated in 61% of cases. In time, 4% of cases progressed to overt cutaneous B-cell lymphoma.¹²⁰³ It is still not clear in what proportion of cases transformation to cutaneous lymphoma occurs and if 'transformation' may in fact represent undiagnosed early cutaneous lymphoma.¹²¹⁹ Transformation to a malignant lymphoma has been reported to occur in 25% of presumed benign lymphoid hyperplasias in which a clonal B-cell population has been identified, compared with 5% of cases without demonstrable clonality.¹²¹⁸

Histopathology

The histological appearances are varied, and there is considerable overlap with primary cutaneous follicle center cell lymphoma and primary cutaneous marginal zone B-cell lymphoma. There is a variably dense infiltrate that may have a perivascular and periappendageal distribution or be more diffuse. The epidermis is usually spared, but some small lymphocytes may be seen in the epidermis.¹²¹² A 'top-heavy' cellular infiltrate is more common than a 'bottom-heavy' one but is not specific (Fig. 41.37). The infiltrate may extend into the subcutis. In reactions at the site of vaccination, the subcutis is predominantly affected with little dermal involvement.^{1205,1206} Lymphoid follicles are present in many but not all cases, and well-developed mantle zones are seen in a minority, which may present a difficulty in distinguishing hyperplasia from follicle center cell lymphoma. The composition of follicles is different from that seen in follicle center cell lymphoma in that centroblasts are more prominent and tingible body macrophages are always present.¹²¹² Stains for follicular dendritic cells may demonstrate follicular aggregates without germinal centers. Fusion of irregular follicle centers may be seen to produce a pattern similar to that in diffuse large B-cell lymphoma.¹²²⁰ Well-formed lymphoid follicles with germinal centers are seen in lesions following vaccination.^{1205,1206}

In some comparative studies, reactive follicles were seen more often in cutaneous marginal zone lymphoma than in reactive lymphoid hyperplasia.^{1219,1221} Between these structures, there is an infiltrate rich in small T lymphocytes with admixed scattered T and B immunoblasts. Eosinophils, histiocytes, and plasma cells may also be present. Granulomas and necrosis can be seen in post-vaccination hyperplasia.¹²⁰⁵

Immunohistochemistry and cytogenetics

The B cells, T cells, and histiocytes mark with the appropriate markers for their lineage. The germinal centers stain for CD10 and are negative for bcl-2. Plasma cells are polyclonal when stained for immunoglobulin light chains. Dendritic cells positive for CD1a and S100 are also present in the infiltrate.¹²¹⁸ Preliminary data suggest that the evaluation of B-cell clonality using the BIOMED-2 PCR system may be useful in distinguishing true cutaneous lymphomas from simulants.¹²²²

Figure 41.37 Cutaneous lymphoid hyperplasia. (A) The infiltrate is 'top heavy' and contains reactive follicles. (B) The germinal centers of reactive follicles contain tingible body macrophages. (H&E)

LYMPHOMATOID DRUG REACTIONS

The atypical lymphoid infiltrates in some cutaneous drug reactions can resemble MF (the so-called 'T-cell pattern of cutaneous lymphoid hyperplasia'). The lesions associated with ingestion of drugs may take the form of solitary plaques, nodules, or multiple lesions with a widespread distribution. In addition, erythroderma simulating Sézary syndrome and a digitate dermatosis-like pattern have been reported. Numerous drugs have been implicated, including phenytoin sodium (hydantoin), carbamazepine, griseofulvin, atenolol, cyclosporine, allopurinol, ACE inhibitors, antihistamines, mexiletine, lisinopril, and valsartan.^{374,638,1223–1229}

Drug reactions do not always occur immediately after commencing a drug, but a short clinical history is more typical of a lymphomatoid drug eruption than true lymphoma.¹¹⁸¹ The lesions usually regress after withdrawal of the drug, but in the case of the anticonvulsants, the lesion may persist for 12 months or more.^{375,1230,1231}

Histopathology

There is an infiltrate in the dermis that may be band-like, resembling MF, or nodular.¹²²³ Lymphomatoid vascular and interstitial granuloma-

tous reactions resembling the granulomatous patterns of MF have been described.^{376,800}

The infiltrate often contains lymphocytes with atypical cerebriform nuclei. There is usually a substantial histiocytic component, particularly in the nodular lesions. Eosinophils and plasma cells are usually sparse or absent, although they may be more obvious in the nodular infiltrates.¹²²⁸

Epidermotropism may be observed, sometimes with Pautrier microabscess-like collections.³⁷⁴ Large CD30⁺ T cells have been reported in the dermal infiltrate in reactions to carbamazepine.¹²³²

In the lymphomatoid vascular pattern, vessel walls are infiltrated by small and large lymphocytes and eosinophils.³⁷⁶

Immunohistochemistry and cytogenetics

The infiltrate consists predominantly of T cells, but rarely B cells predominate. This occurs with some antihistamines¹²²⁸ and thioridazine.¹²³³ Most T cells are CD4⁺, and there is usually no loss of pan-T-cell markers (CD2, CD3, and CD5).¹²³⁴ Loss of expression of CD7 and CD62K has been described in some cases.³⁷⁶

PCR analysis of TCR and IgH genes shows polyclonal infiltrates in most cases.^{1235,1236} In some cases, B-cell or T-cell monoclonality has been identified.^{376,1203}

Figure 41.38 Atypical inflammatory cell infiltrate adjacent to molluscum contagiosum. The large cells are CD30⁺ T cells. (H&E)

REACTIONS RESEMBLING CD30⁺ LYMPHOPROLIFERATIVE DISORDERS

Atypical histological infiltrates with prominent large CD30⁺ cells can occur in a variety of situations,¹¹⁷⁵ including drug eruptions (carbamazepine, gemcitabine, and methotrexate);^{1202,1232,1237} leukemic infiltrates;¹¹⁷⁵ the atypical eruption of lymphocyte recovery;¹²³⁸ viral infections including molluscum contagiosum (**Fig. 41.38**), herpes simplex,¹²³⁹ and lymphoproliferative lesions associated with EBV;¹²⁴⁰ arthropod bites including scabies¹²⁴¹ and tick bites;¹¹⁹² and gold acupuncture.¹²⁴²

PSEUDOLYMPHOMATOUS FOLLICULITIS

Pseudolymphomatous folliculitis is a condition that may mimic a cutaneous lymphoma clinically and folliculotropic MF histologically.²⁵² Lesions occur on the face and are solitary, flat or dome-shaped erythematous papules or nodules up to 1.5 cm in diameter. Regression occurs in some cases after biopsy.

Histopathology

There is a diffuse, predominantly perifollicular infiltrate of lymphocytes with infiltration of follicular structures together with destruction of follicles or hyperplasia of follicular epithelium. Aggregates of histiocytes, or granulomas related to disrupted follicles, are often seen; lymphoid follicles are rarely present. The epidermis is not usually involved. Large atypical lymphocytes and plasma cells can be seen in the infiltrates.^{252,1243}

Immunohistochemistry and cytogenetics

There is a mixture of B and T cells identifiable by conventional markers (CD20, CD79a, CD3, and CD45RO). Either B or T cells may predominate. Plasma cells are polyclonal. In one case, CD8⁺ cells predominated over CD4⁺ T cells in the follicular epithelium. Aggregates of perifollicular dendritic cells that are CD1a⁺ and S100⁺ are characteristic. Cells are negative for EBER-1, and neither B- nor T-cell clonality has been identified by PCR.^{252,1243} A recently described case with otherwise characteristic features of pseudolymphomatous folliculitis featured marked folliculotropism and epidermotropism by T lymphocytes.¹²⁴⁴

Dermoscopy of a lesion of pseudolymphomatous folliculitis has shown multiple perifollicular and follicular yellowish spots, follicular red dots, and arborizing vessels; the differential diagnostic significance of these findings awaits further study.¹²⁴⁵

JESSNER'S LYMPHOCYTIC INFILTRATE

Jessner's lymphocytic infiltrate is a relatively uncommon condition of unknown etiology that was first delineated by Jessner and Kanof in 1953.¹²⁴⁶ It is not regarded by all as a distinct entity,¹²⁴⁷ and some consider it part of the spectrum of lupus erythematosus or polymorphic light eruption (see p. 64).^{1248,1249} It is discussed here because it has been classified as 'pseudolymphoma',¹²²³ although the histology is often not atypical and does not suggest a malignant process. In some cases, it may histologically mimic the infiltrates of chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL).

In this condition, there are asymptomatic erythematous plaques, usually on the face or neck.¹²⁵⁰ The upper part of the trunk and other sites are occasionally involved.¹¹⁸⁶ Men are predominantly affected, but it has been reported in children and in a familial setting. There is a report of a case following the use of a hydroquinone-containing bleaching cream.¹²⁵¹ It has a benign but somewhat unpredictable course. Individual lesions may show central clearing and even regression, but there may be recurrences in the same or other areas. The average duration of the disease is 5 years.

Histopathology

There is a moderately dense perivascular infiltrate involving the superficial and deep vascular plexus as well as infiltrates surrounding pilosebaceous units; the subcutis may be involved. The component cells are predominantly small lymphocytes, although larger lymphocytes and plasma cells may be present.¹²⁵²⁻¹²⁵⁸ Mucin may be seen between collagen bundles.

The epidermis is usually normal with no evidence of atrophy, basal vacuolar change, or follicular plugging. These features together with negative immunofluorescence are said to distinguish this condition from lupus erythematosus. In 10–20% of cases (or more), lupus immunofluorescence is negative.¹²⁴⁸

Immunohistochemistry

There is predominantly a T-cell population with a smaller component of B cells. Clear distinction between cutaneous lupus and Jessner's

lymphocytic infiltrate cannot be made based on relative proportions of B and T cells in lesions.¹²⁵⁹ The cells of CLL are B cells that are CD20⁺, CD5⁺. Tomasini *et al.* found identical arrangements of CD123⁺ and CD2AP⁺ plasmacytoid dendritic cells, in perivascular and periadnexal clusters, in Jessner's lymphocytic infiltrate and tumid lupus erythematosus, suggesting that these two designations represent the same disease.¹²⁶⁰

ACRAL PSEUDOLYMPHOMATOUS ANGIOKERATOMA

This condition was first characterized by Ramsay *et al.*,¹²⁶¹ who gave it the acronym 'APACHE' – acral pseudolymphomatous angio-keratoma of children. A more appropriate name appears to be 'papular angiolymphoid hyperplasia'¹²⁶² because it does not appear to be an angiokeratoma histologically, it occurs in adults as well as children, and it is not always acral in distribution. Clinically, it occurs most commonly in children between the ages of 2 and 13 years,¹²⁶¹ but it has also been described in late adolescence and in adults.^{1263–1265} Lesions are red in color and may take the form of single or multiple red papules that may have a linear configuration.¹²⁶⁶ Most lesions have been reported on the extremities, but they have also been described at other sites.^{1263,1267,1268}

Histopathology

There is a confluent upper dermal infiltrate composed of small lymphocytes, histiocytes, and smaller numbers of plasma cells and eosinophils. Occasional giant cells may be seen. Within the infiltrate, there is a proliferation of small vessels lined by plump endothelial cells. The overlying epidermis is thinned, and there is a basal lichenoid reaction with apoptotic bodies or vacuolar change and exocytosis of lymphocytes.^{1263,1264,1266,1269} Lymphoid follicles have been demonstrated in a linear case.¹²⁶⁶

Immunohistochemistry and cytogenetics

The dermal infiltrate consists of a mix of T and B lymphocytes with characteristic markers: T cells predominate. The T cells are a mix of CD4⁺ and CD8⁺ cells, and the epidermal cells are of similar lineage. In most cases, PCR for TCR and IgH have not demonstrated clonality of T or B cells,¹²⁶⁵ except in one report in which a clonal IgH chain rearrangement was demonstrated.¹²⁷⁰

CUTANEOUS CD8⁺ T-CELL INFILTRATES IN HIV/AIDS

Cutaneous CD8⁺ T-cell infiltrates in HIV/AIDS present as plaques and nodules, predominantly on the face and extremities, or with generalized erythroderma.^{1271,1272} A variant, palpable arciform migratory erythema has also been described.¹²⁷³ Regression may occur after HIV antiviral triple therapy.¹²⁷⁴ Methotrexate has been effective in this condition.¹²⁷⁵

Histopathology¹²⁷¹

In these cases, there is a papillary and mid-dermal infiltrate of small cerebriform lymphocytes or a mixed population of lymphocytes including larger cells. Eosinophils are common in the infiltrate. There is mild epidermotropism and occasionally Pautrier microabscesses. Epidermal changes such as acanthosis and hyperkeratosis may also be present as well as a lichenoid reaction with vacuolar change and apoptotic bodies at the dermoepidermal junction. Papillary dermal fibrosis and granulomas are other changes.

Immunohistochemistry and cytogenetics

The cellular infiltrate consists predominantly of T cells that are CD2⁺, CD3⁺, CD5⁺, and CD8⁺. CD7 and CD4 are expressed by some cells. Clonal TCR gene rearrangements are not present.

MISCELLANEOUS

Several topics are considered in this section. There are some similarities between these entities, although extramedullary hematopoiesis is completely different.

CUTANEOUS INFILTRATES IN POST-TRANSPLANT LYMPHOPROLIFERATIVE DISORDERS (PTLDs)

There is a heterogeneous group of lymphoproliferative disorders, usually of B-cell origin, that occur in the setting of organ transplantation (solid organ or bone marrow) and immunosuppression, particularly with cyclosporin A (cyclosporine) and monoclonal antibody OKT3. The risk of developing this complication overall was 1.2% in a large mixed series of transplants.¹²⁷⁶ It depends on the transplanted organ, the age at transplantation, the immunosuppressive drug regimen,¹²⁷⁷ and the EBV status of the patient prior to transplantation.¹²⁷⁸ The risk is approximately 1% for renal transplants; slightly more than 2% for heart, lung, and pancreas transplants; and 4.3% for liver transplants. The risk is two- or threefold higher in children.¹²⁷⁸ Approximately 80% of PTLDs show evidence of EBV infection.^{1278–1280} Cutaneous lesions in the setting of PTLDs are very uncommon. Of those that are classified as lymphoma, 70% are B-cell and 30% T-cell types.¹⁰⁸⁴ They are more common in men. Lymphomas occur most commonly after the first year of transplantation.¹²⁷⁷ Cutaneous lymphomas occur later after transplantation than do noncutaneous lymphomas.¹⁰⁸⁴ The prognosis is better for B-cell lymphomas than for T-cell lymphomas and is generally worse than that of the corresponding lymphoma in a nontransplant setting.¹²⁸¹

The current WHO classification of PTLDs¹²⁸² is as follows:

- **Early lesions:** Reactive plasmacytic hyperplasia and infectious mononucleosis-like
- **Polymorphic PTLD**
- **Monomorphic PTLD** (classified according to lymphoma type): diffuse large B-cell lymphoma; Burkitt's/Burkitt-like lymphoma; plasma cell myeloma; plasmacytoma-like lesions
- **T-cell neoplasms:** Peripheral T-cell lymphoma, not otherwise specified; other types
- **Hodgkin's lymphoma and Hodgkin's lymphoma-like PTLD.**

The *early lesions* occur most commonly in children and adults who are EBV-naïve at the time of transplantation. Presentation is within the first year after transplantation, and there may be an infectious mononucleosis-like presentation. Immunoblasts in nodal infiltrates are EBV⁺ by immunohistochemistry or *in situ* hybridization. The proliferation is usually polyclonal or oligoclonal. In most cases, there is regression with reduction in immunosuppression. They have a good prognosis. Cutaneous lesions have not been reported in this form.

Polymorphic PTLDs are characterized by a mixed infiltrate consisting of a full range of lymphocytes, including small, intermediate-sized immunoblasts and plasma cells. There is a variable mixture of B and T cells. Most cases show monoclonal IgH rearrangements. EBV is expressed in cells. Clonal cytogenetic abnormalities may also be present. Half of the cases of polymorphous PTLDs regress with reduction of immunosuppression. Some progress and require chemotherapy. Cutaneous cases of this form have been reported; they present as papules, nodules, plaques, or ulcers.^{1283–1286}

In the *monomorphic PTLDs*, there are histological changes sufficient to make a diagnosis of lymphoma. They are divided into B- and T-cell types. Most monomorphic B-cell PTLDs resemble diffuse large cell lymphoma and can exhibit centroblastic, immunoblastic, or anaplastic large cell morphology. The majority express EBV in the large cells and exhibit clonal IgH gene rearrangements. There are often clonal karyotypic abnormalities. The majority do not regress with reduction of immunosuppression, and some do not respond to chemotherapy. EBV⁺ cases have a better prognosis than EBV⁻ cases.

Plasma cell myeloma and plasmacytoma-like PTLT are associated with EBV in approximately 50% of cases. Rare cutaneous presentations of diffuse large B-cell lymphoma and plasmacytoma-like forms have been reported and present as papules or nodules.^{1286–1290}

T- and NK-cell PTLDs are less common than the B-cell types and are usually extranodal. Up to one-third of cases are EBV⁺. A variety of cutaneous T- or NK-cell lymphomas rarely present as PTLTs, including MF, Sézary syndrome, subcutaneous panniculitis-like T-cell lymphoma, adult T-cell leukemia/lymphoma, primary cutaneous anaplastic large cell lymphoma, and peripheral T-cell lymphoma unspecified.^{1281,1291,1292} In one series, they represented 19% of T-cell and NK-cell PTLTs.¹²⁹¹ The lesions present in the usual way for the particular type of tumor.¹²⁸¹

Hodgkin's lymphoma and Hodgkin's lymphoma-like PTLT is a rare category. The infiltrate has the characteristics of Hodgkin's lymphoma including Reed–Sternberg cells in the appropriate inflammatory cell background. Reed–Sternberg-like cells can also be seen in polymorphic PTLTs.¹²⁹³

OTHER LYMPHOPROLIFERATIVE DISORDERS ASSOCIATED WITH IMMUNOSUPPRESSION

Two entities are considered in this section: methotrexate-associated lymphoproliferative disorders and the cutaneous infiltrates (including lymphomas) seen in HIV/AIDS infection.

Methotrexate-associated lymphoproliferative disorders

Patients immunosuppressed with methotrexate for such conditions as rheumatoid arthritis,^{1294,1295} dermatomyositis,^{1294,1296} or psoriasis¹²⁹⁷ may develop lesions similar to those seen in post-transplant lymphoproliferative disorders – that is, large B-cell lymphomas, Hodgkin's lymphoma, or polymorphous PTLT. Approximately 40% are extranodal.^{1298–1300} They are frequently,¹³⁰¹ but not always,¹²⁹⁵ associated with EBV infection and often regress after cessation of methotrexate therapy. Similar lymphoproliferative disorders can arise with cyclosporine therapy for psoriasis.¹²⁹⁷

Rare cases have been reported in the skin and take the form of papules, nodules, and ulcers. Lesions commonly regress after methotrexate is ceased.^{1202,1302}

Histologically, the infiltrates are either monomorphous or polymorphous, similar to PTLTs.^{1202,1302} The infiltrates may be polyclonal or monoclonal and may express EBV.¹³⁰²

Similar lesions have been reported after imatinib mesylate therapy for chronic myeloid leukemia.¹³⁰³

Cutaneous infiltrates in HIV/AIDS

Lymphoproliferative disorders are the second most common malignancy after Kaposi's sarcoma (KS) in HIV/AIDS.¹³⁰⁴ Since the introduction of antiviral therapy, the incidence of lymphoma in this group of patients has decreased along with the incidence of KS.¹³⁰⁵ Although MF is the most common primary cutaneous lymphoma in immunocompetent individuals, it is rare in HIV/AIDS.¹³⁰⁶ Most lymphoprolif-

erative disorders are of B-cell origin. Hodgkin's lymphoma has a markedly increased incidence in these individuals,¹³⁰⁴ and it has an aggressive clinical course.¹³⁰⁷

Lymphomas can be of the type seen in non-immunocompromised individuals, such as diffuse large B-cell lymphoma and Burkitt's lymphoma, but some rare forms occur almost exclusively in this group, including primary effusion lymphoma and plasmablastic lymphoma (discussed previously). There are also nonclonal T-cell proliferations (discussed previously).

EBV is detected in up to 60% of all HIV-related lymphomas.¹²⁷⁹ HHV-8 is implicated in primary effusion lymphoma.¹⁰⁸²

The most common types of primary cutaneous lymphoma in HIV/AIDS are large cell lymphomas, either T or B phenotype. Large T-cell lymphomas have pleomorphic or anaplastic morphology and are CD30⁺.^{1306,1308,1309} They may be EMA⁺ and EBV⁺,¹²⁸⁴ but they are usually ALK⁻.¹³⁰⁶

Large B-cell lymphomas have immunoblastic or centroblastic morphology. Some are CD30⁺, and many express EBV. Cutaneous Burkitt's lymphoma has also been reported rarely.⁷⁷¹

EXTRAMEDULLARY HEMATOPOIESIS

Hematopoiesis takes place in the skin in early embryonic life. This process has also been reported in neonates as a consequence of intra-uterine viral infections (rubella, cytomegalovirus, coxsackievirus, and parvovirus)^{1310–1312} and of congenital hematologic dyscrasias (hemolytic disease of the newborn, 'twin transfusion syndrome', and congenital spherocytosis).^{1313–1315}

In neonates, lesions consist of widespread multiple reddish-blue macules and papules – the so-called 'blueberry muffin syndrome'.¹³¹² In adults, it is a rare complication of myelodysplastic and myeloproliferative disorders (chronic myeloid leukemia).¹³¹⁶ The most common association is with myelofibrosis, particularly after splenectomy.^{1317–1324}

Cutaneous changes include reddish, violaceous or pink macules, papules, nodules, and ulcers.¹³²³ High plasma levels of transforming growth factor (TGF)- β_1 have been reported in one case.¹³²⁵ Extramedullary hematopoiesis has also been reported in pilomatrixomas and cutaneous hemangiomas.¹³²⁶

Histopathology

The dermal infiltrate of extramedullary hematopoiesis consists predominantly of myeloid and erythroid elements (**Fig. 41.39**); sometimes

Figure 41.39 Extramedullary hematopoiesis. Nucleated erythrocytes can be observed in this example (arrows). (H&E)

megakaryocytes are a conspicuous component of the infiltrate.^{1320,1327–1329} Cells in all stages of maturation can usually be found. Often, the infiltrate is perivascular.¹³¹⁸ A variant associated with numerous megakaryocytes is known as ‘sclerosing extramedullary hematopoietic tumor’.^{1316,1330} In this lesion, there are proliferating fibroblasts and collagen as well as hematopoietic elements. It may resemble a fibrohistiocytic tumor. Myeloid elements can be demonstrated with a naphthol AS-D chloroacetate esterase stain (Leder stain).

Immunohistochemistry

Myeloid elements can be demonstrated with immunoperoxidase stains for myeloperoxidase; erythrocyte precursors with glycophorin A (CD235a); and megakaryocytes with factor XIII, factor VIII-related antigen, and CD31.¹³²¹ In the case reported with elevated TGF- β_1 levels in plasma, overexpression of this factor could be demonstrated in hematopoietic precursor cells and fibroblasts.¹³²⁵

Differential diagnosis

The microscopic features of cutaneous extramedullary hematopoiesis in newborns can serve as clues to an underlying systemic condition, particularly a congenital infection or hematologic abnormality. In adults, extramedullary hematopoiesis must be differentiated from chronic myelogenous leukemia. This becomes a particular issue in myelofibrosis-associated extramedullary hematopoiesis, which has a number of features in common with chronic myelogenous leukemia. However, the former is not associated with the Philadelphia chromosome.¹³²⁰ Finding erythroid precursors is of help in recognizing extramedullary hematopoiesis, and the presence of megakaryocytes can also aid in the distinction between this disorder and chronic myelogenous leukemia.^{1319,1320}

INTERDIGITATING DENDRITIC CELL SARCOMA

Of the four different types of dendritic cells found in lymph nodes (histiocytic, fibroblastic, interdigitating, and follicular), two – interdigitating dendritic cells and follicular dendritic cells – are associated with neoplasms that may have cutaneous manifestations. Both interdigitating dendritic cells and follicular dendritic cells serve as antigen-presenting cells. The former are found in T-cell-rich areas of lymph nodes and are involved in stimulating T lymphocytes; the latter are normally found in the germinal centers of lymphoid follicles, near the follicle center cells, where they play a role in stimulating B-cell proliferation and differentiation.

Interdigitating dendritic cell sarcoma (IDCS) is a particularly rare tumor, generally appearing in the literature in single case reports or in small series. It is found mainly in adults (although there are pediatric cases) and has a slight male predominance. Solitary lymph node involvement is a common presentation, but extranodal examples exist. Skin involvement has been reported, although these cases are somewhat difficult to trace because early papers did not use this name but referred to lesions composed of interdigitating cells, interdigitating reticulum cells, or spindle cell tumors of reticulum cell lineage.^{1331–1334} Most reports have described only ‘skin lesions’, with locations including extremities, shoulders, and face.¹³³² The most recent report noted a painful, ulcerated lesion of the right preauricular region.¹³³⁴ One pediatric case presented as a soft tissue mass in the left chest.¹³³⁵ Generalized lymphadenopathy, hepatosplenomegaly, and systemic symptoms have been reported. IDCS is an aggressive neoplasm, with approximately half of patients dying from the disease.

Histopathology

Findings include spindled to ovoid cells that may be arranged in fascicles, storiform, or whorled arrangements; sheets of rounded cells also

occur. The cells have abundant, slightly eosinophilic cytoplasm with indistinct borders; the nuclei are spindled to ovoid with vesicular chromatin and distinct nucleoli. Admixed lymphocytes and plasma cells are usually observed.¹³³⁶ Necrosis is uncommon,¹³³⁷ and the mitotic rate is often low. The cells are S100⁺, vimentin⁺, and fascin⁺ and stain weakly positive for CD68 and CD45RB. They are negative for the follicular dendritic cell markers CD21, CD23, and CD35 (Fig. 41.40). The admixed nodal lymphocytes stain as T cells. Immunoglobulin heavy-chain and T-cell receptor genes are germline.¹³³³ With electron microscopy, the cells have interdigitating cell processes, although true desmosomes are not identified. Complex Golgi and lysosomes can be identified.^{1337,1338}

Differential diagnosis

IDCS can sometimes be confused with melanoma (including metastatic melanoma to lymph nodes), particularly because of its positivity for S100 and weak CD68 expression. Staining for MART-1 or HMB45 would of course support the diagnosis of melanoma, but if those stains are negative, other stains may be required. Especially useful are fascin and CD45RB, which, when positive, support the diagnosis of IDCS. Ultrastructure can also be useful because of the elaborate interdigitating cell processes and lack of melanosomes that characterize the cells of IDCS.^{1334,1337} See the following discussion for the distinction from follicular dendritic cell sarcoma.

FOLLICULAR DENDRITIC CELL SARCOMA

Follicular dendritic cell sarcoma (FDCS) is a rare tumor, with more than 200 cases reported since the first description in 1986.¹³³⁹ It is a disease found mainly in adults, although pediatric cases have been described. Women are prone to develop an inflammatory pseudotumor-like variant.¹³⁴⁰ Lymphadenopathy, especially cervical, is the presenting finding in most cases. FDCS has also been reported to arise in extranodal sites, including the oral cavity, gastrointestinal tract, and soft tissue. It is said that cutaneous involvement occurs, but this is difficult to document; for example, in a 2010 review of 50 Chinese cases, none were reported to involve the skin.¹³⁴¹ However, there has been involvement of the nasopharynx¹³⁴¹ and soft tissues of the neck¹³³⁹ and chest wall,¹³⁴¹ and such lesions could potentially extend to skin. Most often, cutaneous manifestations take the form of paraneoplastic pemphigus, with or without an association with Castleman’s disease^{1342,1343} or an autoantibody-producing thymoma.¹³⁴⁴ The course of FDCS is relatively indolent, but there can be recurrences in half and metastases in one-fourth of cases, sometimes after a long delay.¹³⁴⁰ Cases with high-grade features or in an intra-abdominal location may have a rapidly fatal course. Treatment includes surgery with or without radiation or chemotherapy.

Histopathology

FDCS is composed of spindled to ovoid cells that can be fascicular, storiform, whorled, or arranged in sheets or nodules. The cells have moderate amounts of eosinophilic cytoplasm and oval to elongated nuclei with distinct nucleoli. The lesion can range from an overall bland configuration to one with substantial atypia and relatively brisk mitotic activity. Variants consist of clear or oncocytic cells or cells with hyaline cytoplasm.¹³⁴⁰ The immunophenotype is CD21⁺, CD23⁺, CD35⁺, vimentin⁺, fascin⁺, and clusterin⁺, with variable positivity for S100 and CD68 (Fig. 41.41). In lymph nodes, associated lymphocytes can include B or T cells or both. As with IDCS, IgH and TCR genes are germline. Ultrastructurally, cells have long, slender cytoplasmic processes and may be connected by mature desmosomes.¹³⁴⁰

Figure 41.40 Interdigitating dendritic cell sarcoma. (A) Fusiform to ovoid cells with eosinophilic cytoplasm and nuclei with vesicular chromatin. Scattered small lymphocytes are present. (H&E) The cells are positive for S100 (B) and fascin (C) and negative for CD21 (D). (Immunoperoxidase)

Figure 41.41 Follicular dendritic cell sarcoma. (A) This image shows nodules composed mainly of ovoid cells with rounded to oval nuclei and distinct nucleoli. (H&E) (B) The cells are positive for CD21. (Immunoperoxidase)

Differential diagnosis

The differential diagnosis of FDCS is rather broad and can include squamous cell carcinoma, melanoma, large cell lymphoma, meningioma, malignant fibrous histiocytoma, malignant peripheral nerve sheath tumor, or angiosarcoma. Inflammatory pseudotumor can resemble the inflammatory variant of FDCS, but it lacks cytologic atypia or an aggressive growth pattern and has a polymorphic cell population.¹³⁴⁵ At times, FDCS can closely resemble IDCs; however, it differs because

only FDCS is immunoreactive for CD21, CD23, and/or CD35.¹³³⁷ In addition, electron microscopy shows mature desmosomes only in FDCS.
